This PDF file includes:

Figs. S1 to S16
Tables S1 to S7

SFigure 1: Summary of mass-univariate analyses on null phenotypes (not associated)
A hundred phenotypes were simulated at random and analysed using each model.

SFigure 2: Statistical power for simulated phenotypes associated with a single type of modality
The phenotypes were simulated from a single type of measurement (indicated in parenthesis on the $Y$-axis label). The statistical power is measured using the true positive rate, or proportion of true associations significant after Bonferroni correction.

SFigure 3: Probability of a false positive vertex arising from associations on cortical thickness
The phenotypes were simulated from cortical thickness only. The FWER corresponds to the proportion of replicates with a false positive vertex on each type of measurement.

SFigure 4: Probability of a false positive vertex arising from associations on cortical surface area
The phenotypes were simulated from cortical surface area only. The FWER corresponds to the proportion of replicates with a false positive vertex on each type of measurement.

SFigure 5: Probability of a false positive vertex arising from associations on subcortical thickness
The phenotypes were simulated from subcortical thickness only. The FWER corresponds to the proportion of replicates with a false positive vertex on each type of measurement.

SFigure 6: Probability of a false positive vertex arising from associations on subcortical surface area
The phenotypes were simulated from subcortical surface area only. The FWER corresponds to the proportion of replicates with a false positive vertex on each type of measurement.

SFigure 7: Results of mass-univariate analyses using smoothed meshes of cortical vertices.
For the ease of computation, we only considered a simple simulation scenario of 10 associated vertices (morphometricity of 20\%). Phenotypes were again simulated from the cortical and subcortical meshes, using the same seed vertices and weights as in previous simulations on unsmoothed data.

SFigure 8: Morphometricity estimates of our simulated traits from our two LMM models The grey lines represent the expected values.

SFigure 9: Manhattan plot of mass-univariate vertex-wise analysis of body mass index
The Y axis shows the significance level (-log10 pvalue) for all grey matter vertices using the LMM "single random effect". The red horizontal line indicates the brain-wide significance threshold using Bonferroni correction.

SFigure 10: Manhattan plot of mass-univariate vertex-wise analysis of age
The $Y$ axis shows the significance level (-log10 pvalue) for all grey matter vertices using the LMM "single random effect". The red horizontal line indicates the brain-wide significance threshold using Bonferroni correction.

SFigure 11: Manhattan plot of LMM mass-univariate vertex-wise analysis of sex
The $Y$ axis shows the significance level (-log10 pvalue) for all grey matter vertices using the LMM "single random effect". The red horizontal line indicates the brain-wide significance threshold using Bonferroni correction.

In the "age, sex and ICV adjusted" GLM, we dropped the corresponding covariate when studying age and sex. All adjusted $R^{2}$ are significant (pvalue<1e-16) considering the large sample size. Significance corresponded to a Bonferroni significance threshold of $1.5 e-8$, which accounts for the number of vertices and traits analyses.
