1 Abstract

Enterotoxigenic *Escherichia coli* (ETEC) F4$^+$: O149 is a causative agent for the development of post-weaning diarrhoea (PWD) in pigs that contributes to production losses. Yeast cell wall components used as a feed additive can modulate gut immunity and help protect animals from enteric infections. This work investigated how a novel yeast diet with high inclusion of yeast proteins (40% of crude protein) affected the course of ETEC mediated diarrhoea in weaner piglets from a farm with or without a history of post-weaning diarrhoea. We found that immune response to F4*ab* ETEC infection and appetite of the animals were altered by high inclusion *C. jadinii* yeast. The results indicate that the novel diet can support the diseased animals either directly through the effect of yeast beta-glucans and mannans or indirectly through the promotion of small intestine lactobacilli or both.

2 Introduction

Diarrhoea in neonatal and weaned piglets has been a concern to farmers due to the morbidity and mortality [1, 2]. The introduction of *E. coli* fimbrial vaccines [3] shifted the peak of diarrhoea from the neonatal and suckling period over to the weaning period where the mortality due to diarrhoea is lower [4]. An enterotoxigenic *Escherichia coli* (ETEC) of the O149 serotype has been incriminated in most of the post-weaning diarrhoea (PWD) cases contributing to production losses [2, 5–7]. This enteric pathogen acts via (I) the adhesion to small intestine enterocyte brush border with the help of receptor-specific fimbriae proteins F4 (K88) (*ab*, *ac*, and *ad* variants) and (II) the production of toxins that induce enterocyte electrolyte/fluid imbalance hence watery diarrhoea. However, not all piglets are equally susceptible to ETEC. Some animals are immune to ETEC F4 *ab/ac* colonization due to an inherited trait that is thought to be linked to chromosome 13 of the pig [8]. A 74-kDa glycoprotein (GP74) was found to be key for ETEC adherence [9] but the genetic determinants encoding for this protein are not fully investigated [8, 10, 11]. Polymorphism in the *muc*4 gene was used as a basis for a DNA test to classify animals as either F4-adhesive or F4-non-adhesive [8]. Other candidate genes have been proposed as genetic determinants for the non-adhesive porcine phenotype [11]. The receptors for F4 *ab* fimbriae are found in the small intestine of newborn and weaned piglets [12] but not in older F4-adhesive animals [13]. While nursing piglets are protected from ETEC by maternal transfer of antibodies from vaccinated dams [3, 14], there are currently no measures available to protect piglets against ETEC-mediated diarrhoea after weaning (discussed in [15–17]). Modulation of the immune response against ETEC may be one such solution. Yeast cell wall components, mannans and beta-glucans proved potent immunomodulatory compounds. Fouhse and co-workers demonstrated that supplementation of yeast-derived mannans to weaner pigs positively affected jejunal villi architecture with corresponding changes in the gene expression profile [18]. The findings of Che et. al suggested that yeast mannans in feed could reduce systemic inflammation in pigs via suppression of lipopolysaccharide (LPS) induced TNF-alpha by alveolar macrophages [19]. Stuyven and colleagues reported protective effects of *Saccharomyces cerevisiae*, and *Sclerotium rolfsii* derived beta-glucans against ETEC F4^{+} with a reduction in pathogen shedding and F4-specific serum antibodies in weaner pigs [20]. Our previous work showed that feeding a strain of heat-inactivated *Cyberlindnera jadinii* yeast as a protein source changes the

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. It is made available under aCC-BY-NC-ND 4.0 International license.

55 intestinal microbiota composition in weaner piglets [21]. Using cultivation and 16S *rRNA* gene
56 metabarcoding sequencing techniques, we have shown that the yeast diet promoted the growth of
57 small intestine lactobacilli. Beneficial immunomodulatory properties of intestinal lactobacilli are
58 well documented ([22]; reviewed in [23]). These findings indicate that targeting the lactobacilli
59 populations through diets can have an indirect impact on the host immune response.

60 Because beta-glucans and mannans are structural components of the yeast cell wall, and yeast
61 replaced as much as 40% of the conventional proteins in the experimental diet, we hypothesized
62 that *C. jadinii* yeast as a protein source can modulate the immune response towards ETEC F4$^+$
63 and hence affect the course of PWD in weaner piglets.

64 To test the ability of a *C. jadinii* yeast diet to modify the course of PWD, we recruited piglets from
65 two herds (with and without a history of PWD), primed them with either control or yeast-based
66 diets where 40% of the protein was replaced with yeast, and orally challenged weaned piglets
67 with a haemolytic F4*ab*$^+$ O149 *E. coli* isolated previously from the herd with the history of
68 PWD. To gain insights into the effects of yeast-derived feed, we compared gut microbial ecology
69 metrics (diversity and composition), zootechnical performance, morphology and histology of
70 gastrointestinal (GI) tract focusing on the ETEC F4$^+$ intestinal colonization between the control
71 and the yeast-fed piglet groups.

72 # 3 Results

73 ## 3.1 General information

74 *Post-weaning diarrhoea (PWD)*

75 Of 68 piglets in the experiment, one animal from the control feeding group was euthanized *ad*
76 *hoc* because of circulatory failure on d5 post-weaning (PW). There were no mortality cases due
77 to the bacterial challenge throughout the experiment. Diarrhoea scores were higher for the first
78 three days after the challenge in the piglets from the herd with no history of PWD (F4-naive
79 herd) compared with those of the herd with the history of PWD (F4-immune herd) (Figure 2A).

80 *Average daily gain (ADG)*

81 Average daily gain (ADG) was analysed by fitting the multiple regression model where "day",
82 "litter", and "diet" were the predictor terms (d2 PI was excluded). The analysis revealed that the
83 pigs fed the yeast-based diet tended to gain 62 g/day less weight than those fed the control diet
84 (Figure 2B). The litter contribution to ADG estimate was as follows: litter3283, and litter3286
85 pigs tended to gain 125 g/day less than litter 3282 ($p<0.00001$); litter 3284 was gaining 86 g/day
86 less than litter3282 ($p=0.002$); and litter3287 had 57 g/day greater ADG compared with that of
87 the litter3283 ($p=0.03$).

88 *Feed intake*

89 The feed intake pattern (pen level) diverged between the herds from d3 PI to d5 PI with the
90 F4-immune herd piglets eating more than those of the F4-naive herd. Within the herds, feed
91 intake pattern showed that the control piglets ate more than the yeast fed piglets. From day 8
92 PI onwards, the effect of herd was less pronounced and changes in feed intake were attributed to
93 the diet with the control group eating more feed than the yeast group (Figure 2C).

94 ## 3.2 Immunohistochemistry

95 *F4 and CD3 in the ileum* **d2 PI** The proportion of the mucosa-associated ETEC F4^{+} per length
96 of the ileum epithelium tended to be 5% greater in the pigs fed the yeast based diet than that of
97 the pigs fed control diet (89% posterior probability)(Figure 3A). The piglets from the litter3288

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. Figure 2: Diarrhoea scores and performance results. Panel A: Diarrhoea scores (pen level) across the experimental groups throughout the experiment. Day 7 post-weaning (coloured red) corresponds to the day the animals were orally challenged with ETEC F4$^+$. Panel B: Distribution of the average daily gain (ADG) across the experimental groups at d2, d7, and d14 post-infection. Panel C: Daily feed intake across the experimental groups throughout the experiment. Day 7 post-weaning (coloured red) corresponds to the day the animals were orally challenged with ETEC F4$^+$.

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

98 had 10% less mucosa-associated ETEC F4$^+$ per length of the ileum epithelium than that of the
99 litter3282 (89% posterior probability) (not shown).

100 At d7 PI, the prevalence of F4$^+$ *E. coli* was lower in the ileum of the piglets fed both diets than
101 that of d2 PI. Only two piglets in the yeast group had identifiable counts of F4$^+$ adjacent to the
102 epithelial surface compared with none of the control group. The remaining animals (n=16) were
103 negative for the presence of F4$^+$ *E. coli* in their ileum.

104 There was no clear relationship between neither the diet type, nor the litter, and the proportion
105 of IEL CD3$^+$ cells in the ileum epithelium of the pigs (Figure 3B). However, there was an inverse
106 correlation between the proportion of mucosa-associated F4 antigen and the proportion of IEL
107 CD3 populations in the ileum of the piglets fed the control diet at d2 PI (*rho*=-0.81, 95%CI
108 upper = -0.25, 95%CI lower = -0.94) (Figure 3B). This relationship was not found in the yeast
109 fed piglets (*rho*=0.1, 95%CI upper = 0.58, 95%CI lower = - 0.44) (Figure 3C).

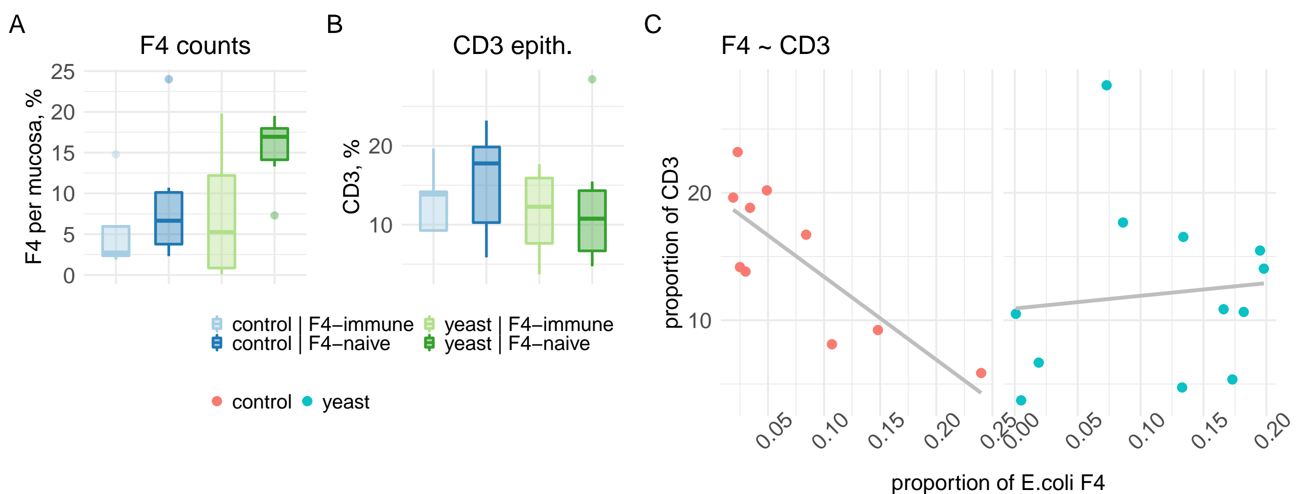

Figure 3: Immunohistochemistry results (d2 PI). Panel A: Distribution of the proportion of the mucosa-associated *E. coli* F4$^+$ per mucosa section (lumen conten excluded) across the experimental groups on d2 PI. Panel B: Distribution of the proportion of IEL CD3$^+$ cells in the epithelium across the experimental groups on d2 PI. Panel C: Correlation between the mucosa-associated F4$^+$ *E. coli* and IEL CD3$^+$ cells in the epithelium of control-fed (red dots) and yeast-fed (blue dots) piglets

3.3 Microbial ecology

3.3.1 Sequencing results

Microbiota profiling was conducted on the ileum (n=63), caecum (n=67), and colon (n=66) digesta contents samples from pigs slaughtered on day 2, 7, and 14 PI (change to PW and same for the graph). Two sequencing runs produced a total of 58,045,034 raw reads. On average there were 71670 (SD=14239) reads per sample after filtering, denoising, and chimera removal (one sample with $<$ 10,000 reads was deleted) (Supplementary Figure 10). Those reads were demultiplexed into 180, 856, and 906 unique amplicon sequence variants (ASVs) per ileum, caecum, and colon datasets, respectively (taxa not seen not more than once in 5% of a dataset were removed).

3.3.2 Alpha diversity

Alpha microbial diversity comparison was made between the diet groups on day 2, 7, and 14 PI using the DivNet method to infer on the Shannon index. The ileum gut microbial communities of the yeast fed pigs were similar on the modelled Shannon index at d2 PI to those of the control diet. On d7 PI the ileum microbiomes of the yeast fed pigs showed a higher diversity than those of the control diet (Figure 4). This difference became more pronounced on d14 PI (Figure 4). As with the ileum, the microbial communities in the caecum of the yeast fed pigs were not different than those of the control at d2 PI. However, the caecal communities of the control diet-fed piglets were more diverse compared with those of the yeast diet (Figure 4).

129 ### 3.3.3 Beta diversity

130 To study the impact of diets on beta microbial diversity in the intestines of ETEC challenged
131 pigs, a multivariate model with permutations was fitted to the phylogeny-informed community
132 data (see methods).

133 **day 2 PI** Although the **diet** was associated with the variance in the microbial communities on
134 d2 PI across the **ileum, caecum, and colon** (R^2 =9%), the **litter** (parental genetics) was a
135 much **stronger predictor** of the variance in the respective microbiomes (R^2=38%) (Figure 5,
136 Supplementary Figure 11).

137 **day 7 PI** The litter could predict 27.9% of the variance in the microbial data from the **ileum**
138 of pigs sampled on d7 PI, while the diet was not a statistically significant predictor of the
139 variance. The proportion of the variance in the microbial data explained by **diet increased**
140 for the large intestine microbiomes at d7 PI (R^2=14.7%) compared with d2 PI. Reciprocally,
141 the **litter** accounted for **less variance** of the unweighted Unifrac distances of the respective
142 microbiomes (**caecum, colon** d7 PI) (R^2=24.2%) than that of d2 PI.

143 **day 14 PI** About the same amount of variance in the unweighted Unifrac distances was accounted
144 by the **diet** across the **ileum, caecum, and colon** at d14 PI (R^2=14.2%), whereas the **litter**
145 **was not** a statistically significant **predictor** of the variance at that time point.

146 ### 3.3.4 Differential abundance test

147 **3.3.4.1 Ileum** Two days after the challenge (d2 PI) there were more *Clostridia* class in the
148 ileum microbiome of the control piglets compared with that of the yeast piglets. *Bacilli*, in
149 contrast, were more predominant in the microbiome of the yeast fed piglets compared with
150 that of the control (Figure 6). At a higher taxonomic resolution, a *Lactobacillus* cluster (sp.
151 *reuteri*, *mucosae*, and *salivarius*) and *Streptococcus luteciae* were more predominant in the yeast
152 microbiomes, while *Sarcina* and *Clostridium* sp. G060 were more predominant in the microbiomes
153 of the control fed piglets.

154 At d7 PI, the differential abundance of *Clostridia* and *Bacilli* bacterial classes was similar to
155 the differential abundance at d2 PI (above). *Gammaproteobacteria* were more abundant in the
156 microbiomes of the ileum of yeast-fed piglets compared to those of the control-fed piglets (Figure
157 6). More specifically, *E. coli*, *Streptococcus luteciae*, *Veilonella dispar*, *Actinobacillus* unclassified.,
158 *Actinobacillus porcinus*, and Pasteurellaceae ASVs were differentially abundant in the yeast-fed
159 microbiomes of the ileum. Of note, *Clostridium perfringens* was more predominant in the ileum
160 of the control diet-fed piglets.

161 At d14 PI, there again were more *Clostridia* class and less *Proteobacteria*, *Actinobacteria*, and
162 *Gammaproteobacteria* bacterial classes in the control-fed ileum microbiomes compared with those
163 of the yeast-fed piglets (Figure 6). At the family level, there were more Enterobacteriaceae,
164 Streptococcaceae, Veillonellaceae, and Pasteurellaceae and less Clostridiaceae in the microbiomes
165 of the yeast-fed piglets than those of the control piglets.

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. It is made available under aCC-BY-NC-ND 4.0 International license.

166 **3.3.4.2 Caecum** At d2 PI there were more *Streptococcus luteciae*, Paraprevotellaceae
167 (CF231), and *Parabacteroides* taxa in the caecal microbiomes of yeast-fed piglets than in those
168 of the control diet (Figure 7). At d7 PI the relative abundance of *Proteobacteria*, *Firmicutes*,
169 *Deferribacteres*, *Actinobacteria*, and *Tenericutes* phyla were higher in the control fed piglet
170 caecum microbiomes compared with those of the yeast (Figure 7). The only phylum that
171 was more predominant in the yeast group caecum microbiomes than that of the control was
172 *Bacteroidetes*. As many as 36 taxa were more predominant in the control fed piglet caecum
173 microbiota compared with 2 taxa in that of the yeast (Figure 7).

174 At d14 PI, the relative abundance of bacterial classes *Deltaproteobacteria* and *Erysipelotrichi*
175 was differentially abundant in the yeast-fed piglet caecum microbiomes compared with those
176 of the control-fed piglets. In contrast, *Epsilonproteobacteria* relative abundance was higher in
177 the control-fed piglet caecum microbiomes compared with those of the yeast-fed piglets. At the
178 species taxonomic level, there were 10 differentially abundant taxa in the control-fed caecum
179 microbiomes compared with 11 of those in the yeast-fed piglets (Figure 7).

180 **3.3.4.3 Colon** At d2 PI, there more *Parabacteroides*, Paraprevotellaceae, Ruminococcaceae,
181 and *Novispirillum* affiliated ASVs in the yeast fed piglet colon microbiomes than in those of the
182 control-fed piglets. The relative abundances of *Campylobacter*, *Prevotella*, and *Desulfovibrio* were
183 higher in the colon microbiomes of the control fed piglets compared with those of the yeast-fed
184 piglets (Figure 8). At the species level of analysis, the relative abundances of *E. coli*, *L. johnsonii*,
185 and *P. copri* were differentially abundant in the colon of control-fed piglets compared with those
186 of the yeast-fed piglets (Figure 8).

187 At d7 PI, the relative abundance of *Proteobacteria*, *Firmicutes*, *Spirochaetes*, *Deferribacteres*,
188 *Actinobacteria*, and *Tenericutes* phyla was higher in the control fed piglet colon microbiomes
189 compared with those of the yeast-fed piglets. *Bacteroidetes* and *Elusimicrobia* phyla were
190 more predominant in the yeast-fed colon microbiomes than those of the control-fed piglets. At
191 the species level, there were 48 differentially abundant ASVs in the colon microbiomes of the
192 control-fed piglets and only 5 of those in the colon microbiomes of the yeast-fed piglets (Figure
193 8).

194 At d14 PI, the relative abundance of the bacterial phyla *Firmicutes* and *Tenericutes* was
195 differentially abundant in the control-fed piglet colon microbiomes compared with those of the
196 yeast-fed piglets. In contrast, *Bacteroidetes* phyla relative abundance was higher in the yeast-fed
197 piglet colon microbiomes compared to those of the control-fed piglets. At the species level, there
198 were 32 differentially abundant taxa in the control-fed piglet colon microbiomes compared with
199 5 of those in the yeast-fed piglet colon microbiomes (Figure 8).

3.4 Microbial network analysis

To characterize further the microbial communities that reside in the small intestine, microbial networks were recovered with the Sparse Inverse Covariance Estimation for Ecological Association Inference approach (SPIEC-EASI) algorithm (see material and methods).

The connectivity in the microbial communities of the ileum of the challenged pigs was sparse irrespective of time. Among the connected nodes, lactobacilli formed cliques more often than other phylotypes. Three members of the yeast fed pig microbiome lactobacilli, *L. mucosae*, *L. reuteri*, and *L. johnsonii*, were connected on d2 PI and d14 PI (Figure 9). *L. mucosae* which decreased in numbers in the digesta of the yeast-fed piglets (Figure 6), became disconnected from the lactobacilli clique on d7 PI (Figure 9). Lactobacilli of the control fed pig microbiomes formed bipartite cliques on d2 and d7 PI which consisted of *L. reuteri* and *L. johnsonii*. On d 14 PI theses two species were not connected (Figure 9)

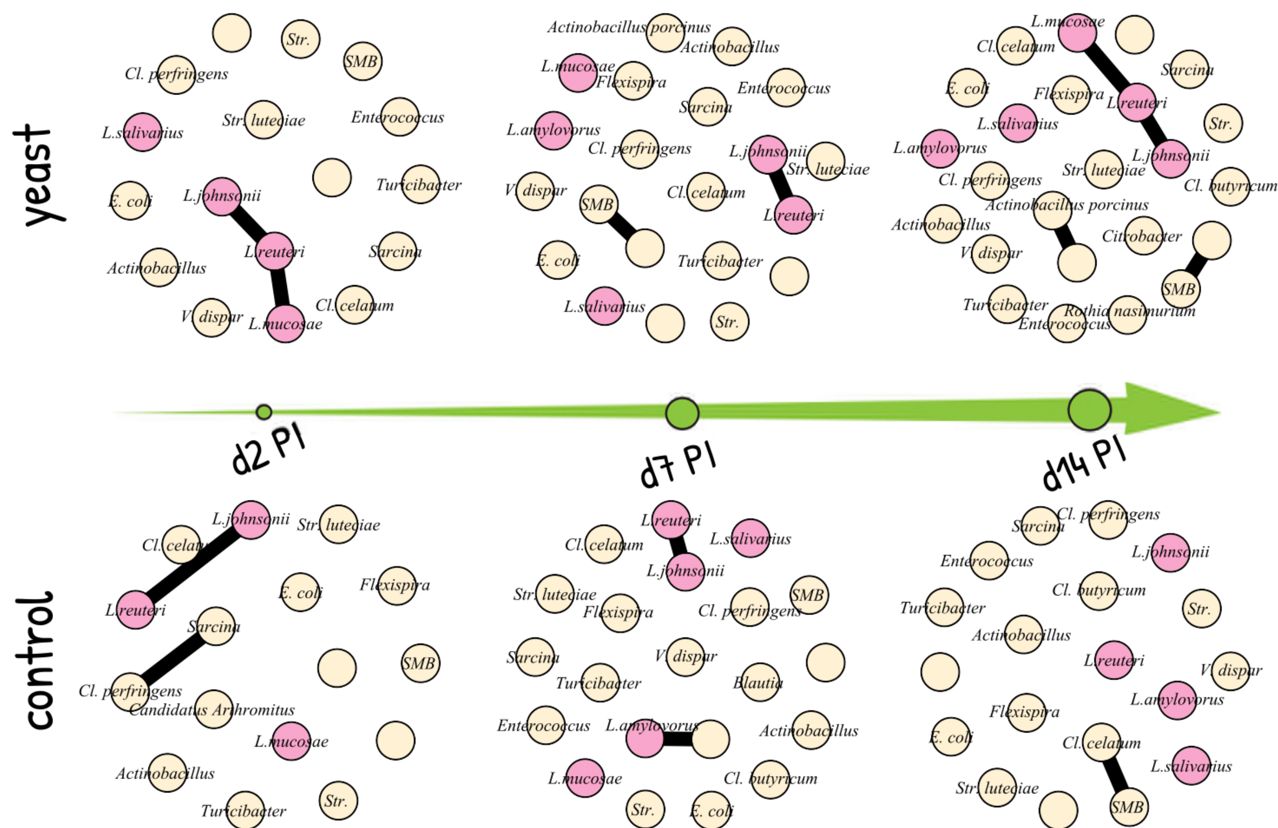

Figure 9: Microbial network of the ileum microbiomes across time and feeding groups. *Lactobacillus* genus is coloured pink, while other taxa are coloured in beige. The nodes (coloured circles) represent ASVs, while the black coloured lines represent connections between the nodes.

212 # 4 Discussion

213 This study investigated the impact of a novel yeast diet on weaner pig immunity assessed in
214 the context of the intestinal microbiome and health parameters. The yeast diet contained
215 beta-glucans and mannans as the structural components of yeast cell walls. Beta-glucans and
216 mannans are believed to possess immunomodulatory properties when supplied to human and
217 other mammals (reviewed in [24, 25]). In this study knowledge about the purity, quantity,
218 and bioavailability of these compounds is limited. The heat deactivated *C. jadinii* yeast cells
219 replaced 40% of crude proteins in the diet. The high dietary inclusion level suggests that large
220 amounts of the immunomodulatory compounds were readily available to the weaned piglets
221 through the experimental diet. A study by Håkenåsen et al. in healthy piglets fed a similar yeast
222 diet demonstrated changes in the immune response in the small intestines by utilizing RNA
223 sequencing analysis. Their findings featured an upregulation of immune signalling pathways,
224 NF-kB and Toll-like receptors, already at d7 PW in the yeast-fed animals [26]. Lagos and
225 co-workers showed that the *C. jadinii* yeast diet was associated with an increased CD3–/CD8+
226 cell population in distal jejunal lymph-nodes at d28 PW. However, the authors did not find this
227 association in the blood [27].

228 In contrast to the studies of Håkenåsen et al. and Lagos et al., the present study employed an *E.*
229 *coli* infection model to elicit changes in the immune response that are attributable to the yeast
230 diet and were not evident in the healthy animal experiments. The choice of the challenge strain
231 (F4ab) used in this study was guided by the relevance of that pathotype for the Norwegian and
232 European swine industry [2, 6, 28]. Once established in a pig farm, the pathogen can remain
233 in the environment for a long time and is hard to eradicate [1, 29]. Another important aspect
234 of this bacterium is that suckling piglets are mostly immune to the infection through colostrum
235 and milk from vaccinated mothers. Sow vaccination shifts the adhesive *E. coli* disease onset
236 to the post-weaning period where piglet mortality due to PWD is lower compared with that
237 of neonates [3, 4]. The reduced growth of the animals due to PWD, however, may be relevant
238 for the industry. From the experimental point of view, this infection model was an appropriate
239 replication of the field disease as the induced infection caused no mortality.

240 The degree of adhesiveness of $F4^{+}$ *E.coli* to porcine enterocytes and subsequently the rate of
241 bacterial colonisation is determined by the genetic constitution of the pigs. One such genetic

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

242 determinants is an SNP located in the *muc*4 gene of porcine chromosome 13. Others have
243 suggested that additional SNP candidates are implicated in F4 susceptibility adhesion porcine
244 phenotypes [11]. To our knowledge, the only DNA based assay that can discriminate between the
245 adhesive and non-adhesive porcine phenotypes is the one developed by Jørgensen and colleagues
246 [8]. The present study involved two principally distinct herds: one with a history of PWD
247 (F4-immune) and another without a history of PWD (F4-naive). The F4-immune phenotype of
248 the pig herds was supported by DNA testing. There were 19 animals in the F4-immune herd
249 that had a mutant allele within the *muc*4 gene compared with none in the F4-naive herd. Our
250 observations of diarrhoea severity due to F4 *E. coli* supported the genotyping results related to
251 F4 susceptibility. The diarrhoea scores were higher in the F4 naive herd piglets from d1 PI to
252 d3 PI. This time-window corresponds to the classical development of PWD [20, 30]. The faecal
253 scores in the F4-immune herd were only slightly elevated post-infection. Feed intake figures also
254 highlighted a lower severity of PWD in the F4-immune herd than that in the F4-naive herd.
255 After the acute phase of the ETEC infection, on d4 PI, the F4-immune piglets were eating more
256 and gaining more weight compared with the F4-naive piglets. One of the key findings in the
257 present study was that the yeast-fed piglets were eating less and subsequently gaining less weight
258 d14 PI than the control-fed piglets. Unlike the figures at d7 PI, the effect of F4 susceptibility on
259 the feed intake and ADG was not pronounced. These findings contrast with previous studies in
260 healthy piglets where feed intake was comparable between yeast-fed and control-fed pigs [26, 31].

261 The implications of appetite loss in yeast-fed animals challenged with a pathogen are unclear. To
262 our knowledge, PWD-affected piglets recover well, and there was no production loss due to the
263 disease on the farm with a history of PWD (the National litter recording system, “Ingris”). It has
264 been proposed that reduced appetite is an adaptation trait which, in concert with the immune
265 response, helps mammals survive enteric infections [32]. Murray and colleagues demonstrated
266 that food avoidance in mice infected with *Listeria monocytogenes* resulted in 50% less mortality
267 compared with the infected force-fed mice [32]. Wang and co-workers [33] obtained similar results
268 by reproducing the experiment by Murray and colleagues [32]. The listeriosis and colibacillosis
269 infection models are not directly comparable concerning the mortality/morbidity rates. The
270 design of this study precludes us from making assumptions on how herds without a history
271 of PWD would fare after being exposed to PWD. However, here we can speculate that the
272 development of appetite loss in the yeast-fed piglets might render pigs more robust against

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

273 possible subsequent infectious stressor. A longitudinal study design, or a field trial, is essential
274 to address this research question.

275 While changes in appetite were observed towards the end of the experiment, changes in the
276 distribution of immune cell populations were already visible at d2 PI. There was an inverse
277 relationship between the intraepithelial CD3 populations located in the ileum and the degree of
278 $F4^+$ *E. coli* colonisation in the control-fed piglets. In contrast, this relationship was not present
279 in the yeast-fed piglets. This finding suggests that the yeast diet enabled intraepithelial T cell
280 populations to persist in the presence of high levels of mucosa-associated $F4^+$ *E. coli*.

281 Our results corroborate and elaborate on the findings of differences in the immune gene expression
282 in the porcine small intestine reported by Håkenåsen et al. [26]. These investigators demonstrated
283 that on day 7 after the introduction of yeast-based feed, several immune system pathways,
284 including Toll-like receptor and NF- appaB signalling pathways, were enriched in the small
285 intestine of the animals. High inclusion levels of immunomodulatory yeast compounds in diets
286 likely stimulates small intestine immunity.

287 It is our speculation that the immune system was (I) modulated prior to the infection either
288 by the immunogenic compounds of the yeast cell walls or shifts in small intestine microbial
289 communities or both and then (II) exposed to antigenic stimuli due to the ETEC infection. This
290 speculation is encouraged by our observations of higher counts of $F4^+$ *E. coli* in the F4-naive
291 herd compared with those of F4-immune herd on the yeast diet. In other words, the growth of
292 intestinal ETEC was suppressed in the pigs from the herd with a history of PWD.

293 These findings indicate the presence of an effect of the yeast diet on the local immune
294 response and, later, on appetite. Hoytema van Konijnenburg et al. using a murine model
295 showed that intestinal intraepithelial lymphocytes (IELs) movements within the epithelium
296 are antigen-specific[34]. The authors demonstrated using live imaging that the IELs increased
297 their motility within the epithelial cell layer ("flossing") when exposed to *Salmonella enterica*
298 antigens. Also, they found that in the absence of pathogen (specific pathogen-free mice) in
299 the lumen the movement of IELs was reduced compared to that of the infected animals. It is
300 difficult to compare our immunohistochemical study to the live cell imaging reported in the
301 work of Hoytema van Konijnenburg and colleagues. While more CD3^+ cells were associated
302 with fewer F4^+ in the control diet-fed pigs and a similar association was not observed in the
303 yeast-fed pigs, a detailed investigation of the dynamics of IEL CD3+ cells in the small intestine

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

during ETEC infection was not performed. It was also beyond the scope of this work to examine the distribution of T cell subpopulations within in the epithelium. It would be interesting to elaborate our preliminary findings to perform a more detailed characterisation of the IEL CD3^+ cells using this infection model.

The gut microbial ecology findings suggest that the pigs may have developed valuable traits after the exposure to the yeast diet and the bacterial challenge. The divergence of gastrointestinal microbiomes over the course of the ETEC infection was quite distinct for pigs fed either the control or yeast diet. On the second day after the ETEC challenge, the small intestine microbiomes of the yeast fed piglets were more diverse with a co-occurrence between *L. johnsonii* and *L. reuteri*, and *L. reuteri* and *L. mucosae*. In addition, *L. reuteri*, *L. mucosae*, and *L. salivarius* were differentially abundant in the yeast fed pig ileum microbiomes on the second day after the ETEC challenge. No major differences in the large intestine microbiomes were identified on the same day. An exception was higher relative abundance of *Str. luteciae* which was present across the ileum, caecum, and colon microbiomes of piglets fed yeast compared with that of the control-fed piglets. The data obtained by Yang and co-workers suggested that *Str. luteciae* was one of the bacterial phylotypes that was more predominant in the healthy piglet faecal microbiomes compared with those of the piglets with diarrhoea (Yang2017). We could not test this trend on our data since the diarrhoea scoring was performed at a group level.

The transition of the gut microbiomes of piglets fed the yeast diet from d2 to d14 PI was characterized by an increase in alpha diversity of the small intestine microbiome compared with those of the control fed piglets. While various phylotypes increased in numbers in the small intestine, the caecum and colon microbiomes of pigs fed the yeast diet were distinct from those of the control diet on d7 PI. A marked drop in a number of bacterial phylotypes, including various dietary fibre degraders (Figure 7, Figure 8), on d7 PI in the yeast-fed piglet large intestine microbiomes coincided with the loss of co-occurrence of *L. reuteri* and *L. mucosae* in the ileum microbial networks. Interestingly, a decrease in *E. coli* coincided with a decrease on d 7 PI in *L. mucosae* in the ileum of piglets fed yeast compared with that of d2 PI. This may suggest that the clearance of the pathogen by the immune system also targeted *L. mucosae*. In contrast, the populations of host-adapted *L. reuteri* and *L. johnsonii* [35, 36] were neither changed in size nor was their co-occurrence pattern disturbed.

When the co-occurrence of *L. mucosae* and *L. reuteri* was re-instated on d14 PI, the caecum, but

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. It is made available under aCC-BY-NC-ND 4.0 International license.

335 not the colon, microbiomes of the piglets fed the yeast diet became more balanced in terms of the
336 differentially abundant phylotypes (Figure 7, Figure 8, Figure 9). The presence of the lactobacilli
337 co-occurrence cluster was another distinct feature of the ileum microbial communities of the
338 yeast-fed piglets. This sub-community was more pronounced in the yeast-fed piglet microbiomes.
339 This distinction in microbial communities may be attributed to the principal differences in the
340 feed formulation. Intact *C. jadinii* yeast cells were fed to animals that cannot enzymatically break
341 down the yeast cell wall components (chitin, mannan-proteins, and yeast beta-glucans). To our
342 knowledge, the ileal digestibility of the yeast feed proteins in weaner piglets is on a par, or higher
343 than that of the proteins from control diets [26, 31]. This means that yeast cell wall disruption
344 is necessary to make yeast intracellular nutrients available for host degradation/uptake. We
345 previously showed that there were more lactobacilli in the small intestine of the yeast-fed healthy
346 piglets compared with that of the control-fed piglets [21]. In the present study, we have also
347 found higher lactobacilli in the ileum and co-occurrence of *L. reuteri* and *L. johnsonii*, and *L.*
348 *johnsonii* and *L. mucosae* in the yeast-fed piglet gut microbiomes. This consistency in identifying
349 more lactobacilli in the small intestine of piglets fed yeast identifies these bacteria as suitable
350 candidates that are instrumental in degrading yeast cell walls. Tannock et al. demonstrated that
351 *L. johnsonii* and *L. reuteri* could co-exist *in vitro*, and in the mouse forestomach. Also, the
352 authors showed that the two strains could adapt nutrient utilization mechanisms depending on
353 whether the strains were alone or in a co-culture. These two lactobacilli strains can degrade mono-
354 and oligosaccharides via several alternative pathways [37, 38]. However, to degrade complex
355 carbohydrates, the bacteria may be obliged to act in concert to maximize nutrient utilization.
356 *In-silico* analysis of a published porcine gut metagenome database [39] shows that *L. johnsonii*
357 can produce mannan endo-1,4-beta-mannosidase, while *L. reuteri* seems to lack the gene. This
358 enzyme may be operative in the degradation of the yeast cell wall mannan-protein complex.

359 Charlet and co-workers demonstrated under laboratory conditions that *L. johnsonii* was able
360 to inhibit the growth of live *Candida glabrata* and *Candida albicans* by exerting a chitinase-like
361 activity [40]. The analysis of porcine metagenomic assemblies [39] revealed that both *L. johnsonii*
362 and *L. reuteri* had a gene encoding a LysM domain which is operative in chitin-binding (reviewed
363 in [41]). While both strains can theoretically bind to the yeast cell walls, only *L. johnsonii*
364 seemed to carry chitinase encoding determinants (GH 18). Based on the existing knowledge and
365 our findings, we argue that yeast cells in the feed undergo lactobacilli microbial degradation in

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

366 the small intestine. We were able to recover a stable connection between *L. johnsonii* and *L.*
367 *reuteri* from all ileal microbiomes except on d14 PI in the control group using the SPIEC-EASI
368 algorithm.

369 The two lactobacilli strains are known to be able to colonize non-secretory epithelia and co-exist
370 in biofilms in the alimentary tract of mammals [36, 38].

371 Based on co-occurrence patterns, our analysis suggests that a distinct lactobacilli phylotype, *L.*
372 *mucosae*, is the third member of the lactobacilli cluster. As all three strains adhere to surfaces
373 and form biofilms [36, 42], we speculate that these lactobacilli cooperate in degrading the yeast
374 cell wall. In support of this notion, *L. mucosae* was never connected to *L. johnsonii* in the
375 microbiomes of piglets fed diets that did not contain the yeast cell substrate. To pursue this
376 notion further, the microscopy of gastrointestinal tract digesta with lactobacillus species-specific
377 labelling may be useful. Our speculation on the possible role of lactobacillus species could
378 be relevant to animal welfare. Lactobacilli are generally thought to be beneficial bacteria of
379 gastrointestinal tract. Since the *C. jadinii* yeast-derived diet can both fulfil nutritional needs
380 of the animals and possibly augment lactobacilli group, the novel yeast diet could enhance the
381 immunity of the animals. In this study, we have demonstrated that yeast-fed piglets showed loss
382 of appetite. This is an evolutionary adaptation that helps animals withstand life-threatening
383 bacterial infections [32, 33].

384 Although it is beyond the scope of this work to study the mechanism of appetite loss, we do
385 not exclude possibility of a complementary effect of yeast immunomodulatory components and
386 intestinal lactobacilli to play a key role. A higher microbial diversity in the small intestine
387 may indicate higher tolerance levels of gut immunity. We also speculate that higher microbial
388 diversity of the ileal microbiomes and caecal microbiomes at d14 PI were linked. It is conceivable
389 that richer microbial communities at d14 PI in the ileum are a function of evolved immunologic
390 resilience boosted by the immunogenic properties of yeast. However, further studies are needed
391 to clarify this suggested interaction.

392 Previous studies have provided evidence that the novel yeast-based diet can support healthy
393 piglets. Irrespective of whether the immune modulation by the yeast diet occurs due to the
394 direct stimulation of the immune system by the yeast beta-glucans and mannans or the indirect
395 stimulation via small intestine lactobacilli growth promotion, or both, the present study shows

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. It is made available under aCC-BY-NC-ND 4.0 International license.

396 that the novel diet can improve the health of diseased piglets in herds with a PWD history.
397 However, the response to such diets on the farm is not always comparable to that under controlled
398 experimental conditions. Furthermore, the immunomodulatory properties of yeast are dependent
399 on the species of yeast and down-stream processing conditions of the yeast [43]. Future work
400 should investigate the effect of yeast strain and down-stream processing on nutritional value and
401 health beneficial effects of yeast, and also assess the performance of novel yeast diets under field
402 conditions.

403 # 5 Ethics statement

404 The animal study was conducted in compliance with the Norwegian Animal Welfare Act
405 10/07/2009 and the EU Directive on the Protection of Animals used for Scientific Purposes
406 (2010/63/EU). Norwegian Food Safety Authority approved the use of animals under FOTS ID
407 16510 protocol.

7 Methods

7.1 Isolation and characterisation of the challenge *E. coli*

The bacterial strain was isolated from a diarrhoea sample of a 31 day old weaner (2 days post-weaning) piglet from a farm with a history of post-weaning diarrhoea (PWD) (described below). The isolate was cultured on blood agar followed by a morphological examination. The bacterial strain was identified as a haemolytic *Escherichia coli* positive for F4 fimbrial antigen as per result of F4(K88) F monovalent rabbit antiserum assay (Statens serum institut, Copenhagen, Denmark). Neo-Sensitabs disc-diffusion antimicrobial susceptibility testing assay(A/S Rosco Diagnostica, Taastrup, Denmark) categorized the strain as being resistant to penicillin, fusidic acid, and streptomycin.

The isolate was propagated on blood agar plate at 37^0C for 24 hours. DNA was extracted using a phenol-chloroform method (https://www.pacb.com/wp-content/uploads/2015/09/SharedProtocol-Extracting-DNA-usinig-Phenol-Chloroform.pdf). The short-read sequencing data were obtained from the Norwegian Veterinary Institute Sequencing unit (SEQ-TECH, VI) (Nextera Flex library prep protocol, Illumina MiSeq 300 bp pair-end sequencing). The long-read data were obtained from Nanopore MinION platform (SQK-RAD004 library prep protocol). Short and long sequencing reads were quality filtered using bbduk version 37.48 (BBMap – Bushnell B., 395 https://sourceforge.net/projects/bbmap/) and Filtlong v0.2.0 (https://github.com/rrwick/Filtlong), respectively. A hybrid (short and long reads) whole-genome assembly was obtained with Unicycler v0.4.8 [44]. The sequenced *E. coli* shared 93.21% genome with *E. coli* UMNK88 NC 017641 (99.81 average nucleotide identity) as per the analysis of the assembled genome using MiGA web-server [45]. Virulence genes of the sequenced *E. coli* were identified using VirulenceFinder 2.0 web-server [46] (https://cge.cbs.dtu.dk/services/VirulenceFinder/). Briefly, the isolate carried genes encoding following virulence determinants: K88/F4, EAST1, heat-labile enterotoxin, and heat-stabile enterotoxin II. The assembled genome was deposited in ENA (ERS5259532).

443 ## 7.2 Experimental design

444 In total, 68 pure Landrace piglets were used in the study. The animals originated from two
445 farms: a) one with a history of recurrent post-weaning diarrhoea (PWD-immune herd, n = 32)
446 and b) one free of PWD problems (PWD-naive, n = 36). Multiparous sows were given "Porcilis
447 Porcoli Diluvac Forte vet." and "Porcilis Ery Parvo vet." (MSD Animal Health, both) before
448 farrowing as a routine vaccination procedure. At day 2 postnatal, piglet oral mucosal swabs
449 were collected followed by DNA extraction using QIAamp DNA Mini Kit (QIAGEN, GmbH,
450 Hilden, Germany). The animals were genotypically classified as being either homozygous
451 (n=48) or heterozygous (n=19) susceptible to F4ac bacterial fimbria adhesion to enterocytes
452 by a *muc*4 gene polymorphism test described previously [8]. Briefly, a DNA fragment of the
453 porcine *muc*4 gene was PCR-amplified (primers: 5'-GTGCCTTGGGTGAGAGGTTA-3' and
454 5'-CACTCTGCCGTTCTCTTTCC-3'), cleaned (NucleoSpin, Macherey-Nagel), and digested
455 with *Xba*I restriction enzyme. The susceptible allele was considered if 151 and 216 bp digestion
456 fragments were obtained. No digestion indicated the resistant allele. The piglets were weaned on
457 day 28 $\pm$ 2 postnatal (average weight of 8.9$\pm$1.5 kg) and transported to the research facility unit
458 where the experiment took place. At weaning, piglets were randomly allocated to either yeast
459 weaner diet or control weaner diet blocking by weight and litter. The resulting four groups,
460 Yeast/PWD-immune, Yeast/PWD-naive, Control/PWD-immune, and Control/PWD-naive,
461 were housed in 4 environmentally controlled pens with dry spruce wood chip bedding (1
462 pen per each group). The bedding material was renewed twice a day. Feed and water were
463 accessible ad libitum at all times. The diet ingredients and chemical composition are given in
464 the supplementary data (Table 1). Piglets were weaned at 28 days of age. After priming to
465 the weaner diets for one week, all piglets were orally inoculated with 10^9 CFU/ml (in 2 ml of
466 Lysogeny broth) of F4-positive enterotoxigenic *E. coli*. Faecal swab samples were taken and
467 cultured on blood agar plates to control for the shedding of the challenge strain before and after
468 the inoculation. The animals were sacrificed on day 2, 7, and 14 post-infection (PI) followed by
469 sampling.

470 ## 7.3 Sample collection

471 Faecal score measurements were taken twice a day throughout the experiment. The faecal scoring
472 system was adopted from [47] which ranged from 1 (firm and shaped) to 4 (watery). The faecal
473 scores were calculated as a mean score per pen per day. Feed leftovers were weighted once a day
474 prior to adding a new portion of the feed. Feed intake was calculated as follows:

475 $\frac{(F - L)}{n}$

476 ,where F is the total weight of feed in the feed dispenser on the day before (g), L is the weight
477 of leftovers on the current day, (g), and n is the number of pigs per pen. Due to the pen level
478 of both faecal scores and feed intake measurements, no statistical procedure was attempted,
479 and the figures were compared directly. Piglets' body weight was taken at weaning, one-week
480 post-weaning (PW), and at each sampling day for those animals who were euthanised to calculate
481 average daily gain (ADG). ADG was calculated as follows:

482 $ADG = \frac{(Ms - Mw)}{D}$

483 ,where Ms is weight at sacrifice (kg), Mw is weight at weaning (kg), and D is the number of days
484 weaning-to-sacrifice (days).

485 ## 7.4 Immunohistochemistry

486 Formalin-fixed, paraffin-embedded (FFPE) tissues were cut into 4-micron thick sections and
487 mounted on glass slides (SuperFrost Plus, Thermo Scientific™, Braunschweig, Germany) and
488 stored at 4°C until staining. The slides were then incubated at 58°C for 30 min, deparaffinized in
489 xylene and rehydrated in graded alcohols to distilled water. Before the labelling with the primary
490 antibodies, heat-induced antigen retrieval was performed. For immunolabelling with CD3
491 antibody, the slides were heated in a microwave in Tris-EDTA pH 9.1 buffer with the following
492 steps, first heated to and held at 92°C for 5 min, thereafter the slides were kept in the heated
493 buffer for 5 min. This cycle was repeated with change in the last step where the slides were kept
494 in the heated buffer for 15 min. For immunolabelling with F4 antibody, the slides were heated in
495 an autoclave at 121°C for 10 min in 0.01M, pH6 citrate buffer. Endogenous peroxidase activity
496 was inhibited with 3% H_2O_2 in methanol for 10 min. Non-specific binding of primary antibody
497 to tissue or Fc receptors was blocked by incubating the slides for 30 min in normal porcine serum
498 at 1:100 in 5% bovine serum albumin (BSA) for CD3 staining and at 1:50 for 20 min for F4

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

499 staining. For labelling of T lymphocytes and Fimbrial adhesin F4, monoclonal anti-porcine CD3
500 clone PPT3 (catalogue number 4510-01, Southern Biotechnology, Birmingham, USA) at 1:1200
501 and polyclonal rabbit anti F4 (catalogue number 51172, Statens serum institut, Copenhagen,
502 Denmark) at 1:400 were used. The slides were incubated at RT for 1 h, followed by 30 min
503 incubation with secondary antibody. Sections labelled for F4 were incubated with secondary
504 antibody from kit polymer-HRP anti-rabbit (Dako En Vision+ System-HRP, Dako, Glostrup,
505 Denmark) while sections labelled for CD3 were incubated with anti-mouse biotinylated secondary
506 antibody (catalogue number BA-2000-1.5 Vector Laboratories, California, United States) at 1:50
507 with 1% BSA and thereafter incubated with Vectastain Elite ABC reagent (Vectastain Elite ABC
508 Kit, Vector Laboratories). Detection of peroxidase activity in the F4 and CD3 slides was detected
509 with AEC + substrate from Dako En Vision+ System-HRP and ImmPACT® AEC Substrate,
510 Peroxidase (HRP) (Vector Laboratories), respectively. For counterstaining, hematoxylin was
511 used and as mounting media Aquatex (Merck, Darmstadt, Germany) was used. For enumeration
512 of F4 and CD3 targes, QuPath, v0.2.3 was used (Bankhead2017). The region of interest (ROI)
513 area was determined for F4 and CD3 and used as a reference for quantification: mucosa and
514 the epithelium of four well-oriented villi, respectively. The detection of positive labelling was
515 performed with the following parameters: Gaussian sigma = 2 um, hematoxylin threshold =
516 0.4, eosin threshold = 0.3. There were three parameters estimated: 1) "F4 counts", that is the
517 proportion of the total number of mucosal surface-associated $F4^{+}$ *E. coli* positive staining to the
518 mucosa ROI, 2) "F4 size", that is the average size of the $F4^{+}$ *E. coli* positive staining areas, or
519 colonies, per the whole area of the section, and 3) "IEL CD3", that is the proportion of CD3
520 positive staining per respective epithelial ROI.

521 7.5 Microbial DNA sample handling

522 At each of the sampling days, 5±1 pigs per pen (12±1 per diet) were euthanised by captive
523 bolt stunning and pithing to allow the collection of gut contents for microbial ecology studies.
524 Digesta from the ileum, caecum, and colon were snap-frozen in liquid nitrogen and stored at
525 -80^{0}C until DNA extraction. Total genomic DNA was extracted from 350 mg of ileum digesta
526 by using QIAamp PowerFecal Pro DNA Kit according to the manufacturer's instructions,
527 except the samples were homogenized using a bead-beating step with zirconia/silica beads (=

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. It is made available under aCC-BY-NC-ND 4.0 International license.

528 0.1 mm, Carl Roth, Karlsruhe, Germany) in TissueLyser II (Qiagen, Retsch GmbH, Hannover,
529 Germany) with the following parameters: 1) pre-cooling of the TissueLyser adaptors down to
530 0^0C 2) bead-beating 1.5 min at 30 Hz. Total genomic DNA was extracted from 300 mg of
531 the caecum and colon digesta by using QIAamp Fast DNA Stool Mini Kit according to the
532 manufacturer's instructions, except the bead-beating step described above and digesting proteins
533 with 30 L of Proteinase K II instead of 15-25 L suggested in the manufacturer's protocol.
534 The purity of extracted DNA was quality controlled by NanoDrop (Thermo Fisher Scientific,
535 Waltham, MA) followed by quantification by Qubit fluorometric broad range assay (Invitrogen,
536 Eugene, OR, USA). Library preparation was performed at the Norwegian Sequencing Centre
537 (https://www.sequencing.uio.no/, Oslo, Norway) using universal prokaryotic primers 319F
538 (5'-ACTCCTACGGGAGGCAGCAG-3') and 806R (5'-GGACTACNVGGGTWTCTAAT-3')
539 that amplify the V3-V4 hypervariable region of the 16S *rRNA* gene. Sequencing was performed
540 on a MiSeq sequencer following the manufacturer's's guidelines. The resulting demultiplexed
541 raw sequences were deposited in the ENA (PRJEB41033).

542 7.6 Bioinformatics analyses

543 Demultiplexed paired-end Illumina reads were pre-filtered with bbduk version 37.48 (https://
544 sourceforge.net/projects/bbmap/) by trimming right-end bases less than 15 Phred quality score,
545 removing trimmed reads shorter than 250 bp or/and average Phred quality score less than 20. The
546 resulting reads were further quality filtered by trimming left-end 20 bp and removing reads with
547 maxEE more than 1 for forward and 2 for reverse reads, denoised, merged, and chimera removed
548 with DADA2 R package ver 1.12.1 [48] (Supplementary Figure 10). The resulting ASV tables
549 that derived from two separate Illumina sequencing runs were merged followed by taxonomy
550 assignment using RDP Naive Bayesian Classifier implementation in DADA2 R package (default
551 settings) with GreenGenes database version 13.8, [49] as a reference database. The phylogenetic
552 tree was reconstructed using phangorn R package ver. 2.5.3 [50] under the Jukes-Cantor (JC)
553 nucleotide model with a gamma distribution (k=4, shape=1) with invariant sites (inv=0.2).

554 DivNet R package [51] was used to estimate Shannon diversity and to test for differences
555 in Shannon diversity estimates in networked gut microbial communities stratified by the day
556 the samples were collected, the gut segment the samples were taken from, with the diet and

bioRxiv preprint doi: https://doi.org/10.1101/2021.02.11.430732; this version posted February 11, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

557 litter as covariates. Shannon entropy estimator of Phyloseq R package was used to calculate
558 Shannon diversity point estimates. To estimate the Shannon diversity index and to compare it
559 across the microbiomes of the pigs fed distinct diets, DivNet statistical procedure was used for
560 each time point. The beta diversity analysis was performed via the analysis of multivariate
561 homogeneity of group dispersions followed by the permutation test (9999 permutations) on
562 unweighted Unifrac distances and principal coordinate analysis (PCoA) on unweighted Unifrac
563 distances, and permutational multivariate analysis of variance (PERMANOVA) test in R, 9999
564 permutations. The samples with the read count less than 40000 were discarded from the alpha
565 and beta diversity analyses.

566 To calculate the relative abundance of bacterial phylotypes in the microbiomes of pigs across diets
567 and time points, group means were taken from the respective groups. To detect differentially
568 abundant bacterial phylotypes, 'corncob' algorithm [52] was run on the microbial feature tables
569 (ASV counts per each sample) by fitting a beta-binomial regression model to microbial data for
570 each time point with the diet and litter as covariates. Benjamini-Hochberg correction (cut-off
571 of 0.05) was used to deal with the false discovery rate due to multiple testing. The test was
572 run at each taxonomic level (phylum, class, order, family, species, and ASVs) discarding the
573 samples with the read count less than 10000. Those ASVs lacking genus/species RDP-derived
574 classifications were attempted to be classified manually by using web-based nucleotide BLAST
575 on the non-redundant nucleotide database, where possible. Ambiguous hits were ignored.

576 7.7 Microbial network analysis, ileum

577 The ASV counts were agglomerated at the genus level and filtered for a minimum of 3 counts per
578 ASV in at least 20% of the samples and at least 50% of the sample per time point (2, 7, 14 days
579 PI) and diet (yeast diet and control diet) using the R package phyloseq version 1.26.1[53]. For
580 each time point and diet, a network was computed on the ileum microbial data with SpiecEasi
581 R package version 1.0.7 [54]. For each recovered network, the edges and nodes were inspected
582 manually.

583 ## 7.8 Statistical analysis

584 Except otherwise specified, the Bayesian generalized linear models with weakly informative priors
585 were fitted through either bayestesteR v0.7.5 [55] or rstanarm v2.21.1 [56]. The results of the
586 statistical analysis were given as a level of certainty of a certain even to be true given the model
587 and available evidence.

8 Supplementary information

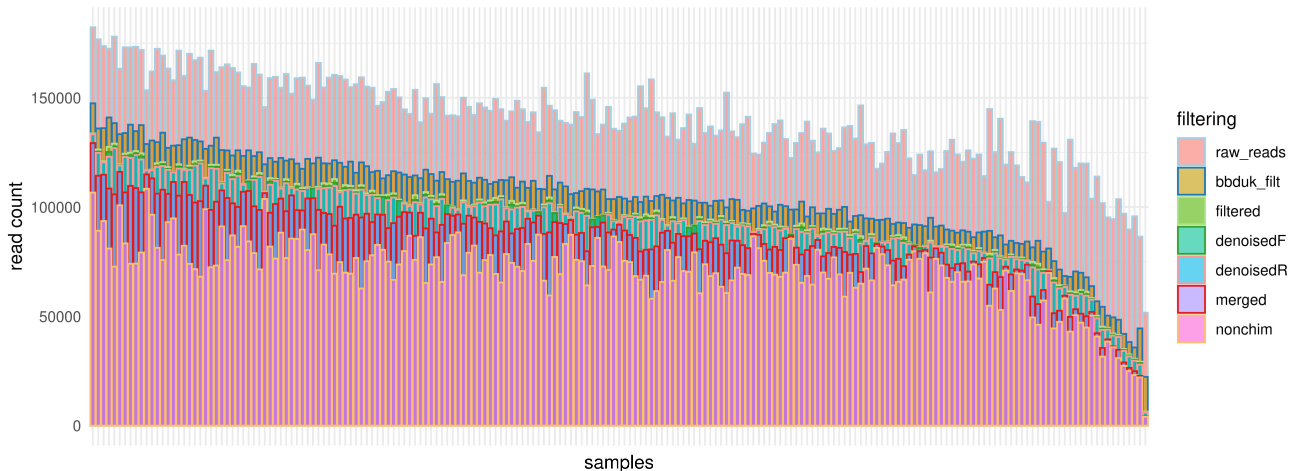

Figure 10: Summary of sequence processing pipeline. The bottom-most bar in the stack (nonchim) shows the number of read that were the basis for making the feature count table (OTU/ASV-table).The bars above nonchim summarise the number of sequencing reads removed at each bioinformatics pipeline step: a) filtered with the bbduk filtering algorithm ($bbdukfilt$), b) filtered with the DADA2 algorithm ($filtered$), c) removed after DADA2 denoising step ($denoisedR/F$), d) removed due to pair merging failures ($merged$). $rawreads$ are raw demultiplexed reads derived from Illumina sequencer.
