8

9 **ABSTRACT**

10 Climate-smart land management practices that replace shallow-rooted annual crop systems with
11 deeply-rooted perennial plants can contribute to soil carbon sequestration. However, deep soil carbon
12 accrual may be influenced by active microbial biomass and their capacity to assimilate fresh carbon at
13 depth. Incorporating active microbial biomass, dormancy and growth in microbially-explicit models can
14 improve our ability to predict soil's capacity to store carbon. But, so far, the microbial parameters that
15 are needed for such modeling are poorly constrained, especially in deep soil layers. Here, we
16 investigated whether a change in crop rooting depth affects microbial growth kinetics in deep soils
17 compared to surface soils. We used a lab incubation experiment and growth kinetics model to estimate
18 how microbial parameters vary along 240 cm of soil depth in profiles under shallow- (soy) and deeply-
19 rooted plants (switchgrass) 11 years after plant cover conversion. We also assessed resource origin and
20 availability (total organic carbon, ^{14}C , dissolved organic carbon, specific UV absorbance, total nitrogen,
21 total dissolved nitrogen) along the soil profiles to examine associations between soil chemical and
22 biological parameters. Even though root biomass was higher and rooting depth was deeper under
23 switchgrass than soy, resource availability and microbial growth parameters were generally similar
24 between vegetation types. Instead, depth significantly influenced soil chemical and biological
25 parameters. For example, resource availability, and total and relative active microbial biomass
26 decreased with soil depth. Decreases in the relative active microbial biomass coincided with increased
27 lag time (response time to external carbon inputs) along the soil profiles. Even at a depth of 210-240 cm,
28 microbial communities were activated to grow by added resources within a day. Maximum specific
29 growth rate decreased to a depth of 90 cm and then remained consistent in deeper layers. Our findings
30 show that > 10 years of vegetation and rooting depth changes may not be long enough to alter microbial
31 growth parameters, and suggest that at least a portion of the microbial community in deep soils can

32 grow rapidly in response to added resources. Our study determined microbial growth parameters that
33 can be used in microbially-explicit models to simulate carbon dynamics in deep soil layers.

38

39 **INTRODUCTION**

40 Soil contains the largest carbon (C) pool in terrestrial ecosystems (IPCC, 2013; Jobbágy and Jackson,
41 2000). Accrual of organic C along soil depth gradients can contribute to climate change mitigation
42 through sequestration of atmospheric carbon dioxide (Paustian et al., 2016). However, most soil C
43 dynamics research so far has focused on the top 30 cm of soil, where soil C concentrations are highest
44 (Jobbágy and Jackson, 2000; Kögel-Knabner et al., 2008). Recent studies highlight that surface soil (< 30
45 cm) and deep soil (> 30 cm) C pools respond differently to changes in environmental conditions (Berhe
46 et al., 2008; Fierer et al., 2003a; Jia et al., 2019; Min et al., 2020; Pries et al., 2017). At the surface,
47 variation in abiotic factors such as temperature and moisture can influence microbial transformation of
48 soil organic C. However, in deeper soil layers, relatively constant environmental conditions, increased
49 mineral interactions, and lower microbial biomass, combined with distinct microbial community
50 composition, may alter the capacity for microbial C transformation relative to the surface (Rumpel et al.,
51 2012; Rumpel and Kögel-Knabner, 2011). Given that most soil C is stored in deep soils (Jobbágy and
52 Jackson, 2000) , we must establish a better understanding of how microbially-driven C dynamics vary
53 along soil depth gradients.

54

55 Microorganisms modify the amount and chemical composition of soil organic matter via decomposition,
56 respiration, growth, and death. Due to the critical roles microbes play in soil C dynamics, several
57 biogeochemical models have recently incorporated microbial parameters (Allison et al., 2010; Salazar-
58 Villegas et al., 2016; Wang et al., 2015; Wieder et al., 2015, 2013). Active microbial biomass and
59 microbial growth rates are both key parameters in microbially-explicit models (He et al., 2015; Zha and
60 Zhuang, 2020), but are poorly quantified because of the technical difficulty of direct quantification
61 (Geyer et al., 2016). Most empirical measurements of microbial biomass reflect total biomass, using

62 analyses made with chloroform fumigation (Anderson and Domsch, 1978; Vance et al., 1987),
63 phospholipid fatty acid (Kao-kniffin and Balsler, 2008; Kohl et al., 2015) or ATP (Contin et al., 2001;
64 Martens, 1995) approaches. However, since total microbial biomass comprises both active and dormant
65 biomass, and active microbial biomass is more relevant to biogeochemical cycles (Couradeau et al.,
66 2019; Geyer et al., 2016; Salazar-Villegas et al., 2016; Singer et al., 2017), using total microbial biomass
67 in models may be inadequate when projecting soil C dynamics. Microbial growth and dormancy can be
68 estimated from growth kinetics models (Mitchell et al., 2004; Panikov and Sizova, 1996), as well as
69 quantitative stable isotope probing (Koch et al., 2018; Pett-Ridge and Firestone, 2017; Schwartz et al.,
70 2016), nucleotide analog tagging (Allison et al., 2008; Hanson et al., 2008), and amino acid-tagging
71 approaches (Couradeau et al., 2019; Hatzenpichler et al., 2014).

72

73 In 1995, Panikov (1995) developed a model that parses microbial respiration sources into growth vs.
74 non-growth related respiration and estimates growth-related parameters (e.g., active vs. dormant
75 microbial biomass, the lag phase before exponential growth, and maximum specific growth rate; See
76 Methods). This approach is useful because it requires readily measurable microbial respiration as an
77 input, and the estimated microbial parameters can be directly used in microbially-explicit models. Using
78 the Panikov model, Blagodatskaya et al. (2014) demonstrated that rhizosphere microbes exhibit a
79 shorter lag time than non-rhizosphere microbes, due to their higher proportion of active biomass and
80 associated lower dormancy. Also, Salazar-Villegas et al. (2016) demonstrated that neither warming nor
81 wetting treatments alter maximum specific growth rates of soil microbial communities.

82

83 Changes in resource availability with soil depth may influence microbial growth parameters. The
84 amounts of organic C, nitrogen (N), and other resources are often higher at the soil surface where inputs
85 from plant litter and root exudates are concentrated (Jobbágy et al., 2001; Rumpel and Kögel-Knabner,

86 2011). In contrast, deeper layers receive limited direct plant inputs; typically, only dissolved organic
87 matter that moves downward through mass flow or diffusion. In addition, mineral-organic matter
88 associations in deeper layers can reduce microbial access to resources (Schmidt et al., 2011). Some
89 studies suggest that soil microorganisms grow faster when resources are more abundant. For example,
90 Blagodatskaya et al. (2010) demonstrated that more C inputs into soils under elevated CO₂ increased
91 microbial maximum specific growth rate.

92
93 Similarly, rhizosphere microbes exhibited greater maximum specific growth rates and shorter lag times
94 than bulk soil microbes (Blagodatskaya et al., 2014). Recent research suggests that these rapid growth
95 responses to resource additions may be driven by traits related to microbial evolutionary history,
96 taxonomy, 16S rRNA gene copy number or genome size (Li et al., 2019; Morrissey et al., 2019). Given the
97 expected decreases in resource availability along soil depth profiles, it is plausible that microbial
98 dormancy increases and the capacity for a rapid growth response declines with soil depth. It is also
99 possible that microbial lag time increases with soil depth because microbes in deeper layers may be
100 more likely to use strategies such as sporulation, and some of the abundant taxa in deep soils have been
101 shown to decrease in relative abundance after soil fertilization (Brewer et al., 2019). Yet, it is unclear
102 how the direction and magnitude of microbial growth parameters vary with soil depth profiles.

103
104 Improved understanding of depth-specific microbial growth kinetics is key for climate-smart land
105 management practices that consider implementation of improved root phenotypes and/or replacement
106 of annual crops with deeply rooted perennials (Paustian et al., 2016). One model deeply rooted species
107 that is being considered in these efforts is switchgrass, a perennial grass native to North America, with a
108 deep rooting system that extends up to 3 m (Liebig et al., 2005; Wright, 2007). Conversion from annual
109 crops to switchgrass can significantly increase deep soil C stocks (Slessarev et al., 2020b). Deeply rooted

110 plant contributions to increased soil C storage are likely tied to changes in the distribution of
111 rhizodeposits, water flow through the soil profile, and the types of microbial communities that thrive in
112 the rhizosphere. For example, in switchgrass fields, enhanced production of extracellular polymeric
113 substances and higher soil aggregate formation have been measured relative to annual crops (Sher et
114 al., 2020), and linked to increased soil C storage with depth (Blanco-Canqui et al., 2005; McGowan et al.,
115 2019; Sher et al., 2020). Also, switchgrass roots increased microbial OTU (operational taxonomic unit)
116 richness along 60 cm of the soil profile (He et al., 2017). To our knowledge, no data currently exists on
117 how the conversion of an annual crop to a deep-rooted perennial crop, such as switchgrass, impacts
118 microbial growth and growth-related parameters (e.g., dormancy, active biomass) in deeper soil layers.
119
120 Here, we investigate microbial growth parameters along soil depth profiles under deeply- (switchgrass)
121 and shallow-(soy) rooted plants. We collected soils under switchgrass and soy plots (n=3, each) from
122 adjacent, paired field locations at soil sampling depths ranging from 0 to 240 cm. We incubated these
123 soils with yeast extract as an added C and energy source, and monitored CO₂ efflux to parameterize a
124 growth kinetics model according to a previously described approach (Blagodatsky et al., 2006; Wutzler
125 et al., 2012). By fitting a growth kinetics model to the CO₂ data, we estimated total and active microbial
126 biomass, maximum specific growth rate, and lag time. In addition, we quantified resource availability
127 prior to the yeast extract addition to explore the interaction of depth and resource availability on
128 microbial parameters. We hypothesized that (1) increasing depth would decrease maximum specific
129 growth rate, due to decreasing resource availability (available C, N), (2) active biomass would be highest
130 in surface soil layers while lag time would be greatest in deep soil layers, due to reductions in resource
131 availability, and (3) microbial growth parameters would be less affected by depth under switchgrass
132 than soy, because greater rooting depth results in more abundant resources inputs at depth.

133

134

135 **METHODS**

136 Study site and soil sampling

137 The study site is located near Bristol, South Dakota (45°16'N, 97°50'W), where switchgrass (*Panicum*
138 *virgatum* L.; cultivar, Sunburst) has been growing since 2008 (Sekaran et al., 2019). Before switchgrass
139 was cultivated, the site was used for soy. The mean annual temperature is 6.3°C, mean annual rainfall is
140 638 mm, and mean annual snowfall is 1092 mm at the nearest weather station in Webster, South
141 Dakota (~32 km away, [https://www.usclimatedata.com/climate/webster/south-dakota/united-](https://www.usclimatedata.com/climate/webster/south-dakota/united-states/usssd0368/2018/1)
142 [states/usssd0368/2018/1](https://www.usclimatedata.com/climate/webster/south-dakota/united-states/usssd0368/2018/1)). The study site is part of a long-term nitrogen (N) addition experiment (0, 56,
143 and 112 kg urea-N ha⁻¹ yr⁻¹ since 2008), however, only control sites (0 kg N) were used for this
144 experiment. The soils are classified as Fine-loamy, mixed, superactive, frigid Calcic Hapludolls (Barnes
145 series, USDA Soil Taxonomy) and Fine-loamy, mixed, superactive, frigid Typic Calciudolls (Buse series,
146 USDA Soil Taxonomy). The parent material is glacial till dominated by fine-grained sedimentary rocks
147 deposited in the upper Pleistocene (Mankato substage, approximately 14 ka before present (Flint,
148 1955)). Each treatment plot is 21.3 m x 365.8 m with a 2-20% slope.

149 In July 2019, we collected a 240 cm deep soil core under switchgrass from each of three non-fertilized
150 plots on a crest landscape position (n=3) using a Geoprobe® 54LT direct push machine (Salina, Kansas,
151 USA) combined with a MC7 system (diameter: 7.62 cm). For comparison, we also collected three 240 cm
152 of deep soil cores in a soy field adjacent to the switchgrass plots (n=3). Since 2008, this field has been
153 primarily used to grow soy and intermittently cropped with other annuals (spring wheat or corn or
154 maintained as pasture (USDA NASS 2020; <https://nassgeodata.gmu.edu/CropScape/>)). After extraction,
155 soil cores were immediately divided into nine sections using a hybrid fixed depth and soil horizon
156 method, i.e., when there was a clear separation between soil horizons by color or texture, we divided

157 sections using a generic horizon approach. Otherwise, we divided soil cores into 20 cm increments for
158 the top 60 cm soil and 30 cm increments for depths below 60 cm. Hereafter, we refer to the soil depth
159 sections as 0-20, 20-40, 40-60, 60-90, 90-120, 120-150, 150-180, 180-210, and 210-240 cm for simplicity
160 of visual representation. After soil cores were subsectioned, we removed rocks and roots manually in
161 the field, shipped the samples to the University of California-Merced in a cooler, and stored them at 4°C.
162 Within a week of arrival, soil samples were processed to determine soil physical, chemical, and microbial
163 properties. In the lab, more roots were hand-picked if necessary. Roots collected from soil cores were
164 dried and weighed to quantify root distribution along soil depth profiles.

165

166 Soil physicochemical properties

167 Soil pH was determined in water (1:5, fresh soil weight:water volume) using a Mettler Toledo pH meter.
168 We extracted dissolved organic C (DOC) by mixing 6 g of fresh soil with 30 mL of 0.5 M K₂SO₄ and shaking
169 the soil solution for 4 h. The soil solution was then centrifugated at 2,000 rpm for 5 min and the
170 supernatant was filtered through a 0.45 µm membrane filter (PALL, Port Washington, NY, USA). The
171 filtrate was stored at -20°C until analysis. The DOC concentration and dissolved N in K₂SO₄ extracts were
172 determined using a VCSH Total OC Analyzer (SHIMADZU, Kyoto, Japan) after thawing in the
173 Environmental Analytical Lab at the University of California-Merced. To estimate the easiness of
174 microbial utilization, we quantified Specific UV Absorbance at 254 nm (SUVA) on K₂SO₄ extracts, using a
175 UV-VIS spectrophotometer (Evolution 300, Thermo Scientific, Massachusetts, USA). Higher SUVA values
176 indicate a higher relative abundance of aromatic compounds in DOC extracts (Weishaar et al., 2003) and
177 less available form of DOC to microbes.

178 Total C and N were quantified on dried and ground soils at the Oregon State University Crop and Soil
179 Science Central Analytical laboratory. Because soils in both vegetation types were alkaline with pH

180 between 8.0 and 9.3 (S1), we treated soils with 1M HCl to remove carbonates before determining total
181 OC concentrations. Inorganic C was quantified at Lawrence Livermore National Laboratory by treating
182 finely-ground subsamples of each sample with 1 M phosphoric acid in a sealed jar and measuring CO₂
183 evolved using a LI-850 infrared gas analyzer (Robertson et al., 1999) for 24 h. Total OC and ¹³C were
184 quantified on acid-treated soils (treatment with 1 M HCl) at the Integrative Biology Center for Stable
185 Isotope Biogeochemistry Lab at the University of California-Berkeley.

186 We assessed radiocarbon values on soils from 0 cm to 150 cm only. Radiocarbon values were measured
187 on the NEC 1.0 MV Tandem Accelerator Mass Spectrometer (AMS) or the FN Tandem Van de Graaff AMS
188 at the Center for Accelerator Mass Spectrometry (CAMS) at Lawrence Livermore National Laboratory.
189 Prior to measurement, acid-treated soils were prepared for ¹⁴C measurement by sealed-tube
190 combustion to CO₂ in the presence of Ag and CuO and reduced onto Fe powder in the presence of H₂
191 (Vogel et al., 1984). The ¹⁴C content of each sample was reported in Δ¹⁴C notation, corrected for mass-
192 dependent fractionation with measured δ¹³C values, and then corrected to the year of measurement for
193 ¹⁴C decay since 1950 (Stuiver and Polach, 1977).

194

195 Soil incubation and CO₂ measurement

196 For soil incubations, 20 g of fresh soil was weighed into a polypropylene incubation jar (McMaster-Carr,
197 473 mL) and pre-incubated at 22°C overnight (108 jars = 2 vegetation types * 9 depths * 3 replicate
198 cores * 2 amendment treatments). For treatment jars, we added 40 mg of powder yeast extract g⁻¹ dry
199 soil as a C and nutrient source (VWR). We chose yeast extract over glucose to provide more varied forms
200 of C and thus stimulate more diverse microorganisms (Fierer et al., 2003b; Slessarev et al., 2020a). A
201 preliminary experiment confirmed that the amount of yeast extract added to the soil was enough to
202 avoid limiting growth during ~10 h of exponential growth phase. After the yeast extract was added, we

203 adjusted the soil water content to 60% of water holding capacity (initial gravimetric water content was
204 $18.6 \pm 3.7\%$) and stirred the soils for 30 s. For control jars, only water was added to soils without yeast
205 extract. The jars were closed with a lid equipped with a non-dispersive infrared CO₂ sensor (CM0126-FS,
206 1% CO₂ sensor, CO₂ meter) (Harmon et al., 2015). We monitored CO₂ concentrations for 10 min every 30
207 to 60 min during the incubation (24~30 h), computed the slope of CO₂ concentration over time, and
208 quantified the microbial respiration rate ($\mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$).

209

210 Microbial growth kinetics

211 We measured microbial growth kinetics using the Panikov model approach, which makes three
212 assumptions (Panikov, 1995; Panikov and Sizova, 1996): First, microbes are not limited by resources (C,
213 water, and nutrients) during incubation. Second, microbial parameters that are estimated from the
214 model refer to those for the initial microbial community, not for the final microbial community after the
215 activation by resources. Three, microbial parameters estimated from the model refer to those from a
216 whole microbial community, undifferentiated among microbial taxa. Under such conditions, microbial
217 respiration follows the equation:

$$218 \quad v(t) = A + B \cdot \exp(\mu_{max} \cdot t)$$

219 Where v is total microbial respiration rate ($\mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$) at time t , A is non-growth respiration
220 of the initial microbial community ($\mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$), B is growth-based respiration of the initial
221 microbial community ($\mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$), μ_{max} is the maximum specific growth rate of the initial
222 microbial community (h^{-1}), and t is the time elapsed since the C and nutrients addition (h). Fitting of this
223 growth kinetics model to our CO₂ data was restricted to the initial exponential growth phase (inflection
224 point) to accurately capture unlimited growth and maximize the goodness of fit r^2 (Wutzler et al., 2012).
225 Physiological status of the initial microbial biomass (relative active biomass) was calculated as below.

226
$$r_0 = \frac{B(1-\lambda)}{A+B(1-\lambda)}$$

227 Where r_0 is relative active biomass of the initial microbial community (unitless) and λ is the ratio of
228 maximum specific rate of growth-related substrate uptake over maximum specific rate of total substrate
229 uptake under unlimited growth. Trutko et al. (1984) demonstrated that the value of λ varied between
230 0.8-0.9 over 100 microbial species. As previous studies exploring microbial growth kinetics have
231 employed $\lambda=0.9$ (Blagodatskaya et al., 2014; Blagodatsky et al., 2006; Panikov and Sizova, 1996), we
232 also used 0.9 for this study. The value of r_0 varies between 0 and 1, with 0 when all microbes are
233 dormant and 1 when all microbes actively grow and divide cells.

234 Total initial microbial biomass was calculated as per the following:

235
$$x_0 = \frac{B \cdot \lambda \cdot Y_{CO_2}}{r_0 \cdot \mu_{max}}$$

236 Where x_0 is the total initial microbial biomass ($\mu\text{g C-biomass g}^{-1}$ dry soil), and Y_{CO_2} is biomass yield per
237 unit CO_2 respired. We acknowledge that Y_{CO_2} can vary with changes in environmental conditions such as
238 temperature and C availability (Lehmeier et al., 2016; Manzoni et al., 2012; Min et al., 2016). However,
239 during the experiment, microbes were allowed to grow under unlimited C and at a constant
240 temperature of 22°C. Thus, we assumed that Y_{CO_2} is constant at 1.5, which corresponds to a commonly
241 observed microbial C use efficiency of 0.6 (Keiblinger et al., 2010; Manzoni et al., 2012; Min et al., 2016).

242 We define lag phase (t_{lag}) as the period when non-growth respiration is equal to or less than growth-
243 related respiration.

244
$$A = B \cdot \exp(\mu_{max} \cdot t_{lag})$$

245
$$t_{lag} = \frac{\ln(\frac{A}{B})}{\mu_{max}}$$

246

247 We assume the longer the lag time is, the higher degree of microbial dormancy. Details about the
248 derivatization and calculation of these growth kinetics equations are provided in previous studies
249 (Blagodatsky et al., 2006; Panikov, 1995; Panikov and Sizova, 1996).

250

251 Statistics

252 Data are presented as mean \pm standard error, where $n = 3$ from replicate cores across soil depth profiles
253 and vegetation types. We fit the Panikov model to the microbial respiration data and estimated
254 microbial growth parameters using a nonlinear least-squares approach (*nls* function in R, R Core Team
255 3.6.3). The effects of vegetation and depth on microbial growth parameters, resource availability, and
256 root biomass were tested using a linear mixed-effects model, with vegetation and depth as explanatory
257 variables and soil core as a random variable (*nlme* package, *lme* (linear mixed effects) function,
258 restricted maximum likelihood method). Depth was treated as continuous. When there was a significant
259 interaction of vegetation type and depth, we used Tukey *posthoc* tests to compare soy and switchgrass
260 values at each depth (*multcomp* package, *glht* (general linear hypotheses) function, Tukey method). All
261 significance was tested at $\alpha = 0.05$.

262

263 **RESULTS**

264 Depth profiles of root biomass and resource availability

265 Increasing depth decreased root biomass for both vegetation types ($p = 0.002$; Fig. 1). No root was
266 detected below 60 cm under soy, while we found roots under switchgrass till 150-180 cm.

267 At a given depth interval, switchgrass produced more roots than soy along soil depth profiles ($p = 0.004$;
268 Fig.1).

269
270 Overall, resource availability declined with soil depth but did not differ between vegetation types (Fig.
271 2). For example, total OC was highest at 0-20 cm for both vegetation types, decreased between 0-20 cm
272 and 40-60 cm, then kept similar below (Fig. 2a). We observed greater total OC concentrations under soy
273 than switchgrass at 0-20 cm. Soil depth decreased ^{14}C values, but vegetation types had little influence on
274 the ^{14}C values (Fig. 2b). Below 90 cm, ^{14}C values approached -1000 per mille, which suggests a mean OC
275 age greater than the geologic substrate's age (Upper Pleistocene ~ 14 ka (Martin et al., 2004)). This likely
276 reflects contributions of fossil OC from the Pierre Shale, a major constituent of glacial till in eastern
277 South Dakota (Flint, 1955), and the underlying bedrock in the region (Tomhave and Schulz, 2004) with
278 an OC content up to several percent (Gautier, 1986; Kennedy et al., 2002).

279
280 DOC significantly decreased with depth and did not vary between vegetation types (Fig. 2c). At 0-20 cm,
281 the average DOC concentration across vegetation types was $113.2 \mu\text{g g}^{-1}$, twice that at 20-40 cm ($p <$
282 0.001). Below 60 cm, the DOC concentration was relatively similar across depths. Depth, but not
283 vegetation type, significantly influenced aromaticity of DOC, measured as SUVA (Fig. 2d).

284 Both total N and dissolved N were significantly influenced by the interaction of depth and vegetation (p
285 < 0.001 and 0.012 , respectively; Fig. 2e,f). At 20-40 cm and 40-60 cm, total N content was higher under

286 soy than under switchgrass ($p = 0.03$ and 0.07 , respectively). In contrast, dissolved N was similar
287 between soy and switchgrass at 0-20 cm, but was significantly higher under soy at depths below 20 cm.

288

289 Microbial respiration

290 Basal respiration, before adding yeast extract, was similar across vegetation and depth (S2). When the
291 data was pooled, the average rate of basal respiration was $0.45 \pm 0.02 \mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$. We
292 observed distinct patterns in microbial respiration after the addition of water (control) versus water plus
293 yeast extract (treatment) to soils (Fig. 3). Water addition did not alter microbial respiration (Fig. 3a),
294 whereas water plus yeast extract immediately enhanced microbial respiration more than ten times (Fig.
295 3b). Then, in the following 30 hours, the yeast extract treatment's respiration rate became relatively
296 stable, increased exponentially, then dropped when all the available resources were consumed.

297

298 Growth parameters

299 We fit the Panikov model to the microbial respiration data to compare microbial growth parameters
300 across depth and vegetation (Fig. 4). Similar to the patterns in resource availability across vegetation
301 and soil depth, we observed a significant depth effect on microbial parameters (except for maximum
302 specific growth rate), but vegetation had little effect on microbial growth kinetics (Fig. 5).

303

304 Total microbial biomass was significantly influenced by depth, but not by vegetation or vegetation and
305 depth interaction (Fig. 5a). When we pooled the data across vegetation, total microbial biomass was
306 $131.8 \pm 9.6 \mu\text{g C g}^{-1} \text{ dry soil}$ at 0-20 cm and decreased by 77% to $30.5 \pm 3.0 \mu\text{g C g}^{-1} \text{ dry soil}$ at 210-240
307 cm.

308

309 Overall, the relative active biomass decreased along soil depth profiles, with a 143 times of reduction
310 from the surface to a depth of 210-240 cm (Fig. 5b). We found that at 40-60 cm, where there was no
311 difference in the total microbial biomass between soy and switchgrass (Fig. 5a), the relative active
312 biomass was two times greater under soy than under switchgrass ($p = 0.04$; Fig. 5b).

313
314 Lag time increased with soil depth profiles (Fig. 5c) and decreased with relative active biomass (S3). The
315 interaction of depth and vegetation significantly influenced lag time (Fig. 5c). At 40-60 cm, the average
316 lag time under soy was 6.1 h, 27% faster than microbes under switchgrass ($p = 0.024$). At 0-20 cm, the
317 lag time was marginally shorter for microbes under switchgrass than those under soy ($p = 0.07$). We
318 observed that microbes at 210-240 cm were activated to grow within 20 h after the yeast extract
319 additions (Fig. 5c).

320
321 Even though the maximum specific growth rate (μ_{\max}) declined between 0 cm and 90 cm ($p = 0.011$),
322 when we included all depths between 0-240 cm, the depth effect was not significant ($p = 0.234$). The
323 average value of maximum specific growth rate was $0.33 \pm 0.01 \text{ h}^{-1}$ across depth and vegetation (Fig.
324 5d). The maximum specific growth rate was independent of microbial biomass, regardless of whether
325 we compared it to total microbial biomass (Pearson's correlation coefficient $r = -0.41$, $R^2 < 0.001$, $p = 0.01$)
326 or relative active biomass (Pearson's correlation coefficient $r = -0.18$, $R^2 = 0.004$, $p = 0.28$).

327
328 Except for maximum specific growth rate, microbial growth parameters had a strong relationship with
329 total OC, DOC, total N, and dissolved N (Table 1). Resource availability was positively related to total and
330 relative active biomass, and negatively related to lag time. The μ_{\max} values had no relationship with any
331 soil chemistry index tested in this study.

332 DISCUSSION

333 Active microbial biomass drives biogeochemical processes (Couradeau et al., 2019; Geyer et al., 2016;
334 Graham et al., 2016; Salazar-Villegas et al., 2016; Singer et al., 2017; Wutzler et al., 2012), but is hard to
335 characterize due to the inefficiency of methods available to extract biomass, especially from deep soil
336 layers, and the possibility of altering microbial physiological status during extraction (Blagodatskaya and
337 Kuzyakov, 2013a). We reduced this limitation by using a growth kinetics model and examined how depth
338 and vegetation type influence microbial growth potentials. To our knowledge, this is the first study to
339 assess microbial growth parameters along deep soil profiles. Overall, we did not observe significant
340 differences in resource availability between vegetation types (see discussion 3 below), thus we primarily
341 focus on the effects of soil depth on microbial parameters. We demonstrate that microbial communities
342 in deep soil layers can grow relatively quickly in spite of significant evidence of dormancy (lower relative
343 active microbial biomass), and that dormancy becomes more common as soil depth increases.

344

345 1. Maximum specific growth rate remains unchanged across 240 cm of soil profiles

346 In this study, maximum specific growth rate was relatively similar across the whole soil profile (0-240
347 cm; Fig. 5d), yielding an average of $0.33 \pm 0.01 \text{ h}^{-1}$. Our estimation is comparable to those observed in
348 other studies; maximum specific growth rate was $0.24\text{-}0.26 \text{ h}^{-1}$ in agricultural topsoils (Blagodatskaya et
349 al., 2014), $0.28\text{-}0.29 \text{ h}^{-1}$ in soil suspension amended with acetate (Van De Werf and Verstraete, 1987),
350 and $0.25\text{-}0.38 \text{ h}^{-1}$ in an Ap horizon of loamy soil (Blagodatskaya et al., 2009). We acknowledge that the
351 third assumption of the Panikov model, the whole microbial community behaves as a single entity (see
352 Methods), is likely to be violated in the real world. This is because distinct microbial taxa often exhibit
353 different physiological properties, including growth rate (Ho et al., 2018; Keiblinger et al., 2010; Koch et
354 al., 2018; Morrissey et al., 2019, 2016). As such, we likely overestimated the whole community growth

355 rate, because relatively slowly growing microbes may have not responded to the yeast extract additions
356 and thus we may have only captured the growth of fast growers.

357 Contrary to our first hypothesis that decreasing resource availability would reduce maximum specific
358 growth rate across the soil profiles, there was no clear relationship between resource availability (C and
359 N) and maximum specific growth rate (Table 1). High resource availability, especially for C, often triggers
360 microbial transition from dormant to potentially active states (Blagodatskaya and Kuzyakov, 2013b;
361 Kovárová-Kovar and Egli, 1998; Lennon and Jones, 2011). Yet, once microbes start growing in response
362 to new resources, antecedent resource availability (i.e., resource availability before adding substrate)
363 may be less relevant to achieving maximum growth rates. Instead, our observation suggests that
364 intrinsic limits of microbial physiology may determine maximum growth potential (e.g., how fast
365 intracellular enzymes catalyze biomolecule synthesis, how constitutively vs. inducibly enzymes are
366 produced)(Adadi et al., 2012), or by the evolutionary history of individual taxa (Morrissey et al., 2019).
367 Although they did not test for maximum specific growth rate, Stone et al. (2014) demonstrated that
368 some extracellular enzymes' biomass-normalized activity does not change with soil depth despite
369 decreasing resource availability along soil depth gradients. Invariant maximum specific growth rates
370 across depth indicate that microbial communities maintain their growth potential regardless of the
371 environmental conditions they inhabit.

372 Relatively invariant maximum specific growth rates across the whole soil profile have two ecological
373 implications. First, the potential for microbial C transformation may be comparable between surface and
374 deep soil layers. Most previous studies exploring microbial activity have focused on surface soils,
375 assuming microbial activity is negligible in deeper soil layers. However, our data suggests microbial
376 communities in deep soils can grow and transform soil C as much as surface microbes do. We
377 acknowledge that we have only limited amount of data at 240 cm, but our data suggest that microbial
378 communities at 240 cm exhibited similar maximum specific growth rate to those at surface soils (Fig.

379 5d). In addition, deep soil microbial communities at 210-240 cm were activated by C addition within 20 h
380 (Fig. 5c) and increased their respiration rate (Fig. 4). Our results are in line with recent findings that
381 microbial C transformations and associated CO₂ fluxes in deep soils (70 cm) are substantial (Min et al.,
382 2020), microbial activities below 30 cm can be as high (Jones et al., 2018) or higher (Stone et al., 2014)
383 than those at the surface. Also, a recent study revealed that root exudates from switchgrass enhanced
384 microbial production of extracellular polymeric substances and soil C stability along 120 cm of soil
385 profiles (Sher et al., 2020). Thus, given the similar maximum specific growth rates across depth profiles,
386 potential microbial C transformation in deep soil layers can be relatively high.

387 Second, model representation of microbial growth across soil depth profiles can be simplified. A growing
388 number of studies demonstrate that including microbial parameters improves model projections of the
389 global C budget (Allison et al., 2010; Salazar-Villegas et al., 2016; Wang et al., 2015; Wieder et al., 2015,
390 2013). However, microbially-explicit models suffer from a lack of empirical knowledge on microbial
391 parameters. Models require information on microbial biomass and biomass-specific rates, as process
392 rates are often expressed as a product of the two (rates = biomass * biomass-specific rates). Our study
393 provides evidence that models may treat microbial growth rate as a constant with soil depth, putting
394 more emphasis on the accurate estimation of microbial biomass. Importantly, it will be critical to
395 quantify active biomass because the active pool of microbes is a better predictor for biogeochemical
396 processes than total biomass (Barnard et al., 2015; Couradeau et al., 2019; Salazar-Villegas et al., 2016;
397 Salazar et al., 2019). In this study, we observed that total biomass was less sensitive to changes in soil
398 depth than relative active biomass. For instance, total biomass decreased by four times while active
399 biomass decreased by 134 times when soil depth changed from 0-20 cm to 210-240 cm (Fig. 5a,b). This
400 suggests that if models employ total biomass, the errors associated with microbial process rates
401 estimation would amplify with soil depth. Empiricists need to use approaches that allow them to

402 distinguish active from total biomass and better inform models of how active biomass would vary when
403 environmental conditions change.

404

405 2. Active biomass decreases, and lag time increases with depth

406 As we hypothesized (second hypothesis), relative active biomass declined, and lag time increased with
407 depth (Fig. 5b,c). Reductions in resource availability likely drove these changes in the relative active
408 biomass and lag time (Table 1). Under conditions with relatively low available resources, microbes may
409 enter dormancy (Lennon and Jones, 2011) or inhabit poorly connected colonies without quorum sensing
410 (Mitri et al., 2016), likely increasing microbial lag time. Our results that deep soil layers contain low
411 available resources (Fig. 2) and relatively low active microbes (Fig. 5b), and that lag time quickly drops at
412 a low range of relative active biomass (S3) highlight that any increases in resource availability would
413 disproportionately influence microbial communities in deep soil layers compared to those in topsoil
414 layers. That is, microbial communities in deep soil layers might quickly shorten lag time if increases in
415 resource availability were to drive increases in relative active biomass.

416 The relative active biomass in this study ranged from 0.02 (=2%) in 0-20 cm soils to 0.0001 (=0.01%) in
417 210-240 cm soils. Our estimates agree with other studies, where active biomass comprised less than
418 0.05% (Salazar et al., 2019), 0.1-2% (Blagodatskaya and Kuzyakov, 2013b), 0.2-0.6% (Blagodatskaya et
419 al., 2009), or less than 3.5% (Bloem et al., 1992) of total biomass. These results imply that soil microbial
420 growth is restricted even at topsoil layers with greatest resource availability, possibly due to lack of
421 signal molecules (quorum sensing)(Atkinson and Williams, 2009) or unbalance in stoichiometry between
422 resources and microbial biomass (Keiblinger et al., 2010; Sterner and Elser, 2002). Dormancy is much
423 more common in soil compared to other systems such as freshwater (~50%) or marine water (~35%)
424 (Lennon and Jones, 2011). This may be due to heterogeneity in soil's physicochemical properties and

425 highly fluctuating environmental conditions (Wallenstein and Hall, 2012; Wang et al., 2014). A great
426 proportion of dormancy in soils may help microbial communities cope with patchy and unpredictable
427 environmental variations and sustain their function over longer timescales (Lennon and Jones, 2011).
428 Many studies demonstrate that active biomass is closely associated with biogeochemical process rates
429 (Salazar-Villegas et al., 2016; Salazar et al., 2019), but we did not detect a clear relationship between
430 active biomass and basal respiration (basal respiration = $0.092 * \text{active biomass} + 0.365$, $R^2=0.12$). One
431 explanation would be extremely low and highly variable basal respiration ($0.45 \pm 0.02 \mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry}$
432 soil h^{-1} ; S2) due to relatively low soil OC (Fig. 2a). In other studies, reported basal respiration is higher
433 than ours, at about $180\text{-}250 \mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$ at 0-15 cm of soil depth in a temperate forest
434 (Salazar-Villegas et al., 2016) and $3\text{-}4 \mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$ from the top 10 cm of a temperate
435 agricultural soil (Blagodatskaya et al., 2014). One study reports comparable values to our estimations at
436 $0.18\text{-}0.24 \mu\text{g C-CO}_2 \text{ g}^{-1} \text{ dry soil h}^{-1}$ in mineral soils (Ritz and Wheatley, 1989). It is plausible that relatively
437 low and variable basal respiration may have decreased our ability to detect differences between
438 vegetation types or among depths, or a relationship between basal respiration and active biomass.

439

440 3. Deeply rooted plants have little effect on microbial growth parameters

441 Contrary to our third hypothesis, vegetation types did not influence microbial parameters in this study.
442 The discrepancy between the expectation and the observations is consistent with our finding that
443 switchgrass did not affect C and N availability (Fig. 2). Although the annual cropland was converted to
444 switchgrass more than a decade ago at our study site (Sekaran et al., 2019) and switchgrass developed a
445 deep rooting system (Fig. 1), the stocks of C and N, and ^{14}C values of bulk soil under switchgrass were
446 not distinguishable from those under soy (Fig. 2).

447 Several scenarios might explain the similar resource availability we observed between vegetation types.
448 First, microbial respiration and priming may be greater under switchgrass than soy, canceling out likely
449 higher plant C inputs from more, longer root growth. Soil C stock is a balance between inputs (litter, root
450 exudates, root turnover) and outputs (respiration). If microbial respiration under switchgrass was
451 enhanced (primed) due to greater plant C input, total soil C stocks may be similar between switchgrass
452 and soy. Yet, similar basal respiration between the two vegetation types (S2) and similar ^{14}C values in
453 bulk soil OC (Fig. 2b) suggest that this scenario is unlikely. Second, despite more, longer root growth
454 under the switchgrass, the amount of root exudates may be comparable between switchgrass and soy.
455 We did not directly quantify root exudates, but similar DOC concentrations between vegetation types
456 (Fig. 2c) suggest that this may be the case. Also, the main function may differ between deep and shallow
457 roots. In a recent review (Lynch, 2019), deep roots are thought to collect water and nitrate, while
458 shallow roots acquire nutrients such as phosphorus, calcium, and potassium. As nitrate is water-soluble,
459 deep roots may not need to release root exudates as shallow roots do to mobilize nutrients. Third, the
460 effects of vegetation and associated changes in the rooting depth on soil C stocks may be minimal in
461 soils with high clay content and alkalinity. Recently, Slessarev et al. (2020b) demonstrated that C stocks
462 were significantly higher under > 10-year-old switchgrass stands relative to annual crops in a low-
463 nutrient sandy soil but found no consistent difference in the amount of C between deeply- and shallow-
464 rooted plants in clayey soil. Soils at our study site were mostly clay loam (approximately 30% clay) with
465 pH higher than 8.0 (S1). Thus, it is plausible that soil conditions may have influenced C accumulation
466 along the soil profiles. Fourth, the annual cropland was fertilized in previous years and soy fixes N from
467 the atmosphere. Contrary to switchgrass, the annual cropland is in rotation between soy and corn, and
468 N fertilizer is used to enhance crop productivity. In addition, soy itself harbors N-fixing bacteria in roots.
469 As such, it is plausible that residual N fertilizer applied in previous years and fixed N may persist to
470 influence resource availability under soy. High dissolved N content under soy along the soil profiles

471 supports this argument (Fig. 2f). Taken together, the conversion from annual crops to switchgrass did
472 not alter resource availability along soil depth profiles at our study site, which, in turn, marginally
473 influenced microbial growth parameters between vegetation types.

474

475 **CONCLUSIONS**

476 Using a growth kinetics model, we estimated microbial growth parameters throughout soil depth
477 profiles, a key knowledge gap for microbially-driven C dynamics models. While other studies have
478 identified significant differences in profile-scale SOC inventories between switchgrass and shallow
479 rooted conventional crops (Ferchaud et al., 2016; Liebigh et al., 2005), in our study site, we did not
480 observe enhanced soil C nor different microbial growth parameters under deep-rooted switchgrass
481 compared to soy. The lack of a detectable plant-cover effect on both SOC stocks and microbial growth
482 capacity may be a function of environmental factors, given that the response of bulk SOC pools to
483 perennial cover can vary considerably as a function of soil properties, environmental conditions, and site
484 history (Blanco-Canqui et al., 2005; Slessarev et al., 2020b). Depth profiles of microbial growth potential
485 revealed increased dormancy rates at depth, but maximum growth potential was relatively similar
486 across soil profiles. This suggests that a component of the microbial community at depth has the
487 potential to rapidly exploit resources introduced by the deep root systems of perennial plants. Thus, to
488 the extent that C inputs from deep root systems can increase SOC stocks, these deep SOC stocks are
489 likely not immune from microbial transformation; rather, they might persist despite the presence of
490 microbial consumers with a high capacity to assimilate fresh C.

491

492

493 **ACKNOWLEDGEMENTS**

494 We thank Drs. Sandeep Kumar and Udayakumar Sekaram at South Dakota State University for allowing
495 us to collect soil samples in their long-term experimental field site. This work was supported by
496 Lawrence Livermore National Laboratory's Lab Directed Research and Development program (#19-ERD-
497 010); the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT;
498 NRF-2018R1A5A7025409); University of California Merced Chancellor's Fellowship to KM; University of
499 California Merced and Falasco Endowed Chair to AAB, and work at LLNL was conducted under the
500 auspices of DOE Contract DE-AC52- 07NA27344.

763 **FIGURE LEGENDS**

764 Fig.1. Depth distribution of root biomass under switchgrass (blue) and soy (orange) in clay-loam
765 agricultural fields in South Dakota.

766 Fig.2. Depth distribution of soil chemistry variables measured in switchgrass (blue) and soy (orange)
767 clay-loam agricultural fields in South Dakota: (a) total organic carbon; (b) ^{14}C ; (c) dissolved organic
768 carbon; (d) specific UV absorbance of dissolved organic carbon (an index of aromaticity of dissolved
769 organic carbon); (e) total nitrogen; (f) dissolved nitrogen. (n=3, error bars represent ± 1 standard error).

770 Fig.3. An example plot of soil microbial respiration from an agricultural soil incubated with (a) water only
771 or (b) yeast extract plus water. The red dashed line indicates the time when water or yeast extract plus
772 water was added.

773 Fig.4. Fitted model of microbial respiration from agricultural soil incubated with yeast extract for
774 switchgrass (left) and soy (right) soils from 0 - 240 cm soil profiles. We used a growth kinetics model
775 described in Panikov (1995). Different colors indicate different depth intervals. For visual simplicity,
776 error bars have been omitted.

777 Fig.5. Depth distribution of microbial growth parameters estimated from a growth kinetics model in
778 Panikov (1995), measured in switchgrass (blue) and soy (orange) soils incubated with yeast extract: (a)
779 total microbial biomass before exponential growth; (b) relative active biomass before exponential
780 growth, which varies between 0 and 1. If 0, all the biomass is dormant. If 1, all microbes actively grow
781 and divide; (c) lag time, the response time of microbial community respiration rates to the additions of
782 yeast extract; (d) maximum specific growth rate (μ_{max}), the maximum microbial growth potential per unit
783 biomass per unit time (n=3, error bars represent ± 1 standard error).

784

785 **TABLES**

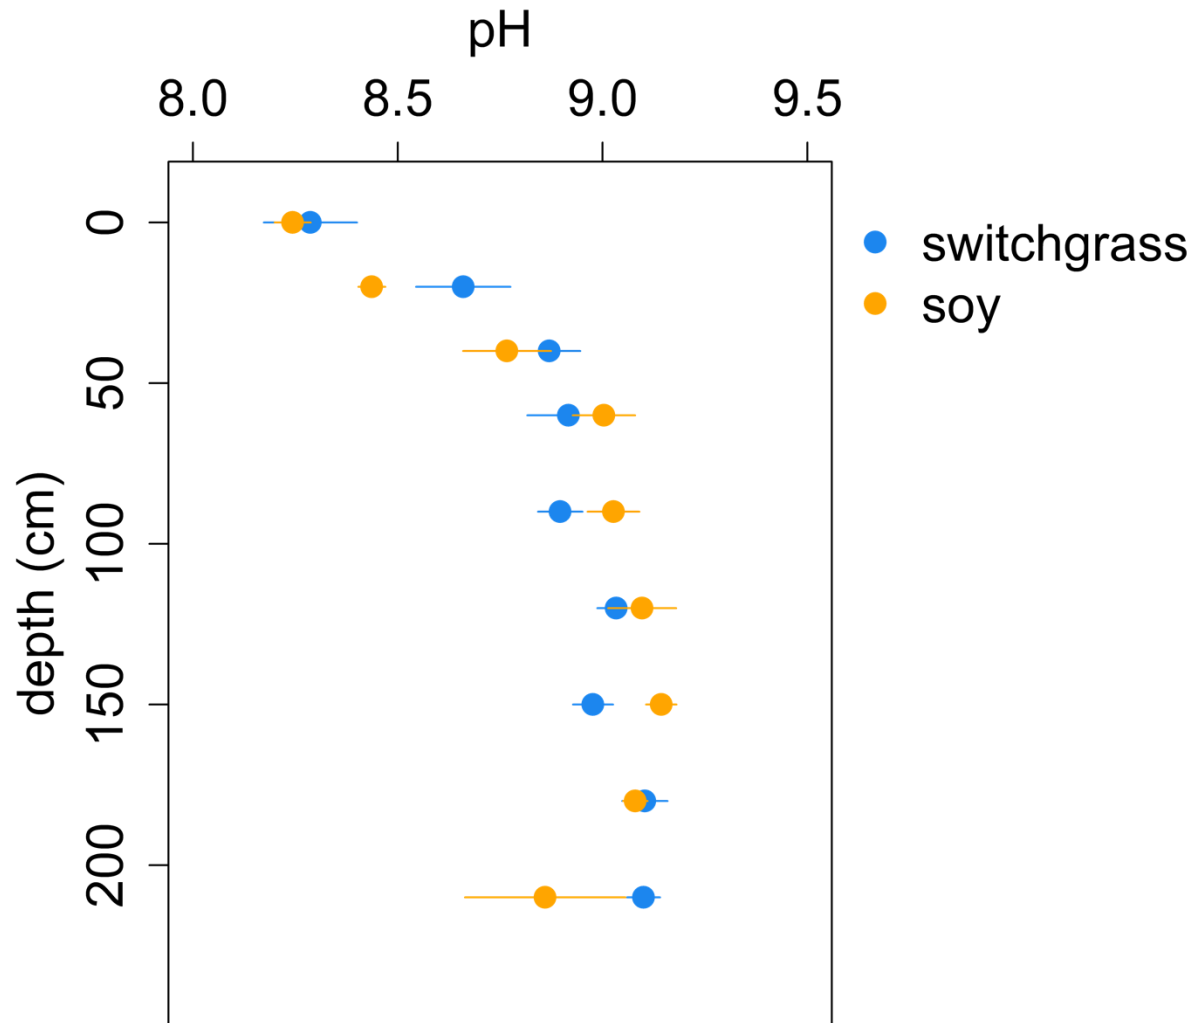

786 Table 1. Pearson's correlation coefficient between growth kinetics parameters and soil chemistry.

	OC	DOC	SUVA	N	Dissolved N
Total biomass	0.47	0.46	0.09	0.49	0.41
Relative active biomass	0.63	0.75	0.28	0.60	0.76
Lag time	-0.70	-0.70	-0.25	-0.63	-0.59
μ_{\max}	0.31	0.22	0.12	0.26	0.15
