1 Abstract

2

3 **Background:** Annotation ambiguities and annotation errors are a general challenge in
4 genomics. While a reliable protein function assignment can be obtained by
5 experimental characterization, this is expensive and time-consuming, and the number
6 of such Gold Standard Proteins (GSP) with experimental support remains very low
7 compared to proteins annotated by sequence homology, usually through automated
8 pipelines. Even a GSP may give a misleading assignment when used as a reference:
9 the homolog may be close enough to support isofunctionality, but the substrate of the
10 GSP is absent from the species being annotated. In such cases the enzymes cannot be
11 isofunctional. Here, we examine a variety of such issues in halophilic archaea (class
12 Halobacteria), with a strong focus on the model haloarchaeon *Haloferax volcanii*.

13 **Results:** Annotated proteins of *Hfx. volcanii* were identified for which public
14 databases tend to assign a function that is probably incorrect. In some cases, an
15 alternative, probably correct, function can be predicted or inferred from the available
16 evidence but this has not been adopted by public databases because experimental
17 validation is lacking. In other cases, a probably invalid specific function is predicted
18 by homology, and while there is evidence that this assigned function is unlikely, the
19 true function remains elusive. We list 50 of those cases, each with detailed
20 background information so that a conclusion about the most likely biological function
21 can be drawn. For reasons of brevity and comprehension, only key aspects are listed
22 in the main text, with detailed information being provided in a corresponding section
23 of the Supplementary Material.

24 **Conclusions:** Compiling, describing and summarizing these open annotation issues
25 and functional predictions will benefit the scientific community in the general effort
26 to improve the evaluation of protein function assignments and more thoroughly detail
27 them. By highlighting the gaps and likely annotation errors currently in the databases,
28 we hope this study will provide a framework for experimentalists to systematically
29 confirm (or disprove) our function predictions or to uncover yet unexpected functions.

1 INTRODUCTION

Haloferax volcanii is a model organism for halophilic archaea (Hartman et al., 2010, Schulze et al., 2020, Leigh et al., 2011, Perez-Arnaiz et al., 2020, Soppa, 2011, Haque et al., 2020), for which an elaborate set of genetic tools has been developed (Allers et al., 2010, Allers and Mevarech, 2005, Kiljunen et al., 2014). Its genome has been sequenced and carefully annotated (Hartman et al., 2010, Pfeiffer et al., 2008a, Pfeiffer and Oesterhelt, 2015). A plethora of biological aspects have been successfully tackled in this species, with examples including DNA replication (Perez-Arnaiz et al., 2020); cell division and cell shape (Turkowsky et al., 2020, Walsh et al., 2019, de Silva et al., 2021, Duggin et al., 2015, Liao et al., 2021); metabolism (Brasen and Schonheit, 2001, Johnsen et al., 2009, Pickl et al., 2012, Sutter et al., 2016, Reinhardt et al., 2019, Kuprat et al., 2021, Kuprat et al., 2020, Sutter et al., 2020, Tästensen et al., 2020); protein secretion (Abdul-Halim et al., 2020, Abdul Halim et al., 2018, Abdul Halim et al., 2013, Storf et al., 2010); motility and biofilms (Schiller et al., 2020, Pohlschroder and Esquivel, 2015, Li et al., 2020, Collins et al., 2020, Quax et al., 2018, Nussbaum et al., 2020); mating (Shalev et al., 2017); signalling (Braun et al., 2019); virus defence (Maier et al., 2019); proteolysis (Reuter and Maupin-Furlow, 2004, Reuter et al., 2010, Prunetti et al., 2014, Cerletti et al., 2018, Cerletti et al., 2014, Costa et al., 2018); posttranslational modification (N-glycosylation; SAMPylation)(Cao et al., 2015, Kaminski and Eichler, 2014, Tripepi et al., 2012, Schulze et al., 2021, Shalev et al., 2018, Kandiba et al., 2016); gene regulation (Qi et al., 2016, Rawls et al., 2010, Hattori et al., 2016, Hwang et al., 2017, Johnsen et al., 2015, Tästensen et al., 2020, Reinhardt et al., 2019); microproteins (Zahn et al., 2021, Nagel et al., 2019, Kubatova et al., 2020) and small noncoding RNAs (sRNAs) (Straub et al., 2009, Heyer et al., 2012, Babski et al., 2014, Wyss et al., 2018).

Genome annotations are frequently compromised by annotation errors (Schnoes et al., 2009, Pfeiffer and Oesterhelt, 2015, Promponas et al., 2015, Danchin et al., 2018). Many of these errors are caused by invalid annotation transfer between presumed homologs, which, once introduced, are further spread by annotation robots. This problem can be partially overcome by using a Gold Standard Protein (GSP) based annotation strategy (Pfeiffer and Oesterhelt, 2015). Because the GSP has itself been subjected to experimental analysis, its annotation cannot be caused by an invalid

annotation transfer process. The GSP strategy had already been applied to a detailed analysis of the metabolism of halophilic archaea (Falb et al., 2008). However, with decreasing level of sequence identity, the assumption of isofunctionality becomes increasingly insecure. Although this may be counterbalanced by additional evidence, e.g. gene clustering, experimental confirmation would be the best option for validation of the annotation.

There are additional and much more subtle genome annotation problems. In some cases, GSPs are true homologs and the annotated function in the database is correct. Nevertheless, the biological context in the query organism makes it unlikely that the homologs are isofunctional, e.g. when the substrate of the GSP is lacking in the query organism. Also, paralogs may have distinct but related functions, which cannot be assigned by sequence analysis but may be assigned based on phylogenetic considerations. Here, again, experimental confirmation is the preferred option for validation of the annotation. Lack of experimental confirmation may keep high-level databases like KEGG or the SwissProt section of UniProt from adopting assignments based on well-supported bioinformatic analyses, so that the database entries continue to provide information that is probably incorrect. We refer to annotation problems in these databases solely to underscore that the biological issues raised by us are far from trivial. There is no intention to question the exceedingly high quality of the SwissProt and KEGG databases (UniProt, 2021, Kanehisa et al., 2019) and their tremendous value for the scientific community. We have actively supported them by providing feedback and encourage others to do the same, e.g. with the recently implemented “Add a publication” functionality in UniProt entries, that allows users to connect a protein to a publication that describes its experimental characterization (<https://community.uniprot.org/bbsub/bbsubinfo.html>).

In this study, we describe a number of annotation issues for haloarchaea with a strong emphasis on *Hfx. volcanii*. We denote such cases as ‘open annotation issues’ with the hope of attracting members of the *Haloferax* community and other groups working with halophilic archaea to apply experimental analyses to elucidate the true function(s) of these proteins. This will increase the number of Gold Standard Proteins

which originate from *Hfx. volcanii* or other haloarchaea, reduce genome annotation ambiguities, and perhaps uncover novel metabolic processes.

2 MATERIALS AND METHODS

2.1 Curation of genome annotation and Gold Standard Protein identification

The Gold Standard Protein based curation of haloarchaeal genomes has been described (Pfeiffer and Oesterhelt, 2015). Since then, a systematic comparison to KEGG data was performed for a subset of the curated genomes (Pfeiffer et al., 2020). The *Hfx. volcanii* genome annotation is continuously scrutinized, especially when a closely related genome is annotated (Tittes et al., 2021). The 16 haloarchaeal genomes that are currently under survey are listed in Suppl. Table S11.

2.2 Additional bioinformatics tools

Key databases were UniProtKB/Swiss-Prot (UniProt, 2021), InterPro (Hunter et al., 2009), KEGG (Kanehisa et al., 2019), and OrthoDB (Kriventseva et al., 2019). The SyntTax server was used for inspecting conservation of gene neighbourhood analysis (Oberto, 2013). As general tools the BLAST suite of programs (Johnson et al., 2008, Altschul et al., 1997) was used for genome comparisons.

3 RESULTS

Open issues are organised below under the subsections (3.1), the respiratory chain and oxidative decarboxylation; (3.2), amino acid metabolism; (3.3), heme and cobalamin biosynthesis; (3.4), coenzyme F420; (3.5), tetrahydrofolate as opposed to methanopterin; (3.6), NAD and riboflavin; (3.7), lipid metabolism; (3.8), genetic information processing, and (3.9), stand-alone (miscellaneous) cases.

3.1 The respiratory chain and oxidative decarboxylation

In the respiratory chain, coenzymes that have been reduced during catabolism (e.g. glycolysis) are reoxidized, with the energy being saved as an ion gradient. The textbook example of a respiratory chain are the five mitochondrial complexes (Rich and Marechal, 2010, Guo et al., 2018): complex I (NADH dehydrogenase), complex II (succinate dehydrogenase), complex III (cytochrome bc_1 complex), complex IV (cytochrome-c oxidase as prototype for a terminal oxidase) and complex V (F-type ATP synthase). In mitochondria, a significant part of the NADH which feeds into the respiratory chain originates from oxidative decarboxylation: conversion of pyruvate to acetyl-CoA by the pyruvate dehydrogenase complex and conversion of alpha-ketoglutarate to succinyl-CoA by the homologous 2-oxoglutarate dehydrogenase complex. While complex I and II transfer reducing elements to a lipid-embedded two-electron carrier (ubiquinone), the bc_1 complex transfers the electrons to the one-electron carrier cytochrome-c, a heme (and thus iron) protein, which then transfers electrons to the terminal oxidase.

Bacteria like *Escherichia coli* and *Paracoccus* have related complexes and enzymes: NADH dehydrogenase (encoded by the *nuo* operon), succinate dehydrogenase (encoded by *sdhABCD*) and the related fumarate reductase (encoded by *frdABCD*) (Crofts et al., 2013), several terminal oxidases (e.g. products of *cyoABCDE*, *cydABC*), and an F-type ATP synthase (encoded by *atp* genes). *E. coli* lacks a bc_1 complex, which, however, occurs in *Paracoccus denitrificans* (Kaila and Wikstrom, 2021). *E. coli* contains the canonical complexes of oxidative decarboxylation (pyruvate dehydrogenase complex, encoded by *aceEF+lpdA*, and 2-oxoglutarate dehydrogenase complex, encoded by *sucAB+lpdA*).

149

150 The respiratory chain of *Hfx. volcanii* and other haloarchaea deviates considerably
151 from those of mitochondria and bacteria such as *Paracoccus* and *E. coli* (reviewed by
152 (Schafer et al., 1999)), and a number of questions remain unresolved. We focus on the
153 equivalents of complex I, III and IV, because these have unresolved issues. We also
154 cover some aspects relevant for NADH levels (oxidative decarboxylation enzymes
155 and type II NADH dehydrogenase). We do not cover complexes that have already
156 been studied in haloarchaea: complex II (succinate dehydrogenase) (Scharf et al.,
157 1997, Sreeramulu et al., 1998, Gradin et al., 1985) and complex V (ATP synthase)
158 (Steinert et al., 1997, Nanba and Mukohata, 1987).

159

160 (a) In haloarchaea, oxidative decarboxylation is not linked to reduction of NAD to
161 NADH but to reduction of a ferredoxin (encoded by *fdx*, e.g. OE_4217R, HVO_2995)
162 which has a redox potential similar to that of the NAD/NADH pair (Kerscher and
163 Oesterhelt, 1977). The enzymes for oxidative decarboxylation are pyruvate--
164 ferredoxin oxidoreductase (*porAB*, e.g. OE_2623R/2622R, HVO_1305/1304) and 2-
165 oxoglutarate--ferredoxin oxidoreductase (*korAB*, e.g. OE_1711R/1710R,
166 HVO_0888/0887), and these have been characterized from *Halobacterium salinarum*
167 (Plaga et al., 1992, Kerscher and Oesterhelt, 1981b, Kerscher and Oesterhelt, 1981a).

168

169 (b) In *Hfx. volcanii*, ferredoxin Fdx (HVO_2995) plays an essential role in nitrate
170 assimilation (Zafrilla et al., 2011). It may well be involved in additional metabolic
171 processes and it is yet unresolved how ferredoxin Fdx is reoxidised, but this might be
172 achieved by the Nuo complex.

173

174 (c) The *nuo* cluster of haloarchaea resembles that of *E. coli*, with genes and gene
175 order highly conserved, and just a few domain fissions and fusions. However,
176 haloarchaea lack NuoEFG (Falb et al., 2005), which is a subcomplex mediating
177 interaction with NADH (Leif et al., 1995, Braun et al., 1998). Thus, the haloarchaeal
178 *nuo* complex is unlikely to function as NADH dehydrogenase, despite its annotation
179 as such in KEGG (as of April 2021).

180

181 (d) Other catabolic enzymes generate NADH, which also must be reoxidized. Based
182 on inhibitor studies in *Hbt. salinarum*, NADH is not reoxidized by a type I but rather
183 by a type II NADH dehydrogenase (Sreeramulu et al., 1998). A gene has been
184 assigned for *Natronomonas pharaonis* (Falb et al., 2008). However, for reasons
185 detailed in Suppl.Text.S1, this assignment is highly questionable, so that this issue
186 calls for experimental analysis.

187

188 (e) About one-third of the haloarchaea, especially the *Natrialbales*, do not code for a
189 complex III equivalent (cytochrome bc₁ complex encoded by *petABC*) according to
190 OrthoDB analysis. The bc₁ complex is required to transfer electrons from the lipid-
191 embedded two-electron carrier (menaquinone in haloarchaea) to the one-electron
192 carrier associated with terminal oxidases (probably halocyanin). How electrons flow
193 in the absence of a complex III equivalent is currently unresolved.

194

195 The haloarchaeal *petABC* genes resemble those of the chloroplast b6-f complex rather
196 than those of the mitochondrial bc₁ complex (see Suppl.Text S1 Section 1 for more
197 details).

198

199 (f) A bc cytochrome has been purified from *Nmn. pharaonis*, but with an atypical 1:1
200 ratio between the b-type and c-type heme (Scharf et al., 1997). The complex is
201 heterodimeric, with subunits of 18 kDa and 14 kDa. The 18 kDa subunit carries the
202 covalently attached heme group (Scharf et al., 1997). An attempt was made to identify
203 the genes coding for these subunits (Mattar, 1996) (for details see Suppl.Text S1
204 Section 1). Two approaches were used to obtain protein sequence data, one being N-
205 terminal protein sequencing of the two subunits extracted from a SDS-polyacrylamide
206 gel. In the other attempt, peptides from the purified complex were separated by
207 HPLC, and a peptide absorbing at 280 nm (protein) as well as 400 nm (heme) was
208 isolated. Absorption at 400 nm clearly indicates covalent attachment of the heme
209 group to the peptide. The sequences from the two approaches overlapped and resulted
210 in a contiguous sequence of 41 aa, with only the penultimate position remaining
211 undefined (Mattar, 1996). Based on this information, a PCR probe was generated

(designated “cyt-C Sonde”) that allowed the gene to be identified and sequenced, including its genomic neighbourhood. It turned out that the genes coding for the four subunits of succinate dehydrogenase (*sdhCDBA*) had been isolated. The obtained protein sequence corresponds to the N-terminal region of *sdhD* (with the initiator methionine cleaved off) and only 2 sequence discrepancies in addition to the unresolved penultimate residue.

In the PhD thesis (Mattar, 1996), this unambiguous result was rated to be a failure (and the data were never formally published). The reason is that SdhD is free of cysteine residues, while textbook knowledge states that a pair of cysteines is required for covalent heme attachment (Kletzin et al., 2015). The lack of the required cysteine pair was taken to indicate that the results were incorrect and that the identified genes did not encode the cytochrome bc that the study had been seeking (Mattar, 1996). In contrast, we speculate that the results were completely correct, despite being in conflict with the cysteine pair paradigm. In our view, a paradigm shift is required. The obtained results call for a yet unanticipated novel mode of covalent heme attachment, exemplified by the 18 kDa subunit of *Natronomonas* succinate dehydrogenase subunit SdhD. It should be noted that the 41 aa protein sequence, which had been obtained, turned out to contain three histidine residues upon translation of the gene, but none of these had been detected upon Edman degradation.

In *Halobacterium*, a small c-type cytochrome was purified (cytochrome c₅₅₂, 14.1 kDa) (Sreeramulu, 2003). Heme staining after SDS-PAGE indicated a covalent heme attachment, but no sequence or composition data were reported, so that it is not possible to identify the protein based on the available information. We speculate that the *Halobacterium* cytochrome c₅₅₂ also represents SdhD (as detailed in Suppl.Text S1 Section 1). In that case, the proposed novel type of covalent heme attachment would not be restricted to *Nmn. pharaonis* but might be a general property of haloarchaea. This would also solve the “*Halobacterium* paradox” (Kletzin et al., 2015).

(g) The haloarchaeal one-electron carrier is the copper protein halocyanin rather than the iron-containing heme protein cytochrome-c. A halocyanin from *Nmn. pharaonis* (NP_3954A) has been characterized, including its redox potential (Mattar et al., 1994, Scharf and Engelhard, 1993, Hildebrandt et al., 1994). A gene fusion supports the close connection of a halocyanin with a subunit of a terminal oxidase. For further details see Suppl.Text S1 Section 1.

(h) Terminal oxidases are highly diverse in haloarchaea and we restrict our analysis to three species (*Nmn. pharaonis*, *Hfx. volcanii*, and *Hbt. salinarum*) because in each of these at least one terminal oxidase has been experimentally studied (Table 1). Details are described in Suppl. Text S1 Section 1.

(i) NAD-dependent oxidative decarboxylation is a canonical reaction to convert pyruvate into acetyl-CoA, and alpha-ketoglutarate into succinyl-CoA. In haloarchaea, the conversion of pyruvate to acetyl-CoA and alpha-ketoglutarate to succinyl-CoA is dependent on ferredoxin, not on NAD (see above). Nevertheless, most haloarchaeal genomes also code for homologs of enzymes catalyzing NAD-dependent oxidative decarboxylation, such as the *E. coli* pyruvate dehydrogenase complex. In most cases, the substrates could not be identified, an exception being a paralog involved in isoleucine catabolism (Sisignano et al., 2010). In several cases the enzymes were found not to show catalytic activity with pyruvate or alpha-ketoglutarate (see Suppl.Text S1 Section 1 for details). Also, a conditional lethal *porAB* mutant was unable to grow on glucose or pyruvate, thus excluding that alternative enzymes for conversion of pyruvate to acetyl-CoA exist in *Hfx. volcanii* (Kuprat et al., 2021). Nonetheless, despite experimental results to the contrary, pyruvate is assigned as substrate for some of the homologs of the pyruvate dehydrogenase complex in KEGG (as of April 2021).

271
 272 Table 1: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 1)**. The column Section refers to the
 273 Table listing the protein and to the section in the Results and in Suppl. Text S1. As an example, 2c covers topic (c) from the decimal-numbered
 274 Results subsection 3.2 Amino Acid Biosynthesis. In Suppl. Text S1, this is covered under Section S2 subsection S2.c. The corresponding
 275 proteins are listed in Table 2. For a few proteins, two sections are indicated (e.g. 1a/1b). The column Code refers to a haloarchaeal protein by its
 276 locus tag, which is mainly from *Haloferax volcanii* (HVO), but also from *Halobacterium salinarum* (OE), *Natronomonas pharaonis* (NP) and
 277 *Halohasta litchfieldiae* (halTADL). When the reconstruction of a complete pathway is presented, the unassigned genes are indicated as a
 278 “pathway gap”. In one case we indicate the absence of a haloarchaeal ortholog by a dash. In the case of a complex, we either list more than one
 279 code, or we list only one subunit together with the term (complex). All subunits of these complexes are listed groupwise in Table S10. A protein
 280 may be shown in more than one row. From the 2nd row onwards, this is indicated by the term (cont.). The column Gene lists the assigned gene or
 281 a dash if no gene has been assigned. The assigned gene is only indicated in the first row of a protein. A set of four columns is used to relate a
 282 query protein to an experimentally characterized homolog, a GSP (Gold Standard Protein) (isofunc, %seq_id, Locus tag, UniProt). The column

283 isofunc indicates if the query protein and its Gold Standard Protein homolog are isofunctional. The meaning of the terms used in this column in
284 Tables 1-9 (yes, no, yes/no, probably, possibly, unclear, unknown, prediction, special, “-“) is described at the end of this legend. The column
285 %seq_id indicates the protein sequence identity between the query protein and the homologous GSP. The column Locus tag contains the locus
286 tag, if assigned. The column UniProt contains the UniProt accession of the GSP. GSPs have been experimentally characterized as described in a
287 publication. The column Reference links to the reference list of the manuscript. The column PMID lists the PubMed ID of the publication, if
288 available. Otherwise, this is indicated as “not in PubMed”. Also, one PhD thesis is indicated (PhD_Matter). The column Comment provides
289 various types of additional information. The terms used in the column isofunc in Tables 1-9 have the following meaning: The term “yes”
290 indicates that we consider the two proteins as isofunctional and annotate the query protein accordingly. The term “no” is used when we conclude
291 that the proteins differ in function. Additional terms are used for more difficult cases. The term “yes/no” is used for GSPs which are
292 multifunctional, and we assign only one a subset of these functions to the query protein. The term “probably” is used when we consider
293 isofunctionality likely and annotated the query protein accordingly (with the term probable added to the protein name). The term “possibly” is
294 used when we see a good chance that the proteins are isofunctional, but consider it too speculative to annotate the protein accordingly. The term
295 “unclear” is used when we consider it likely that the same overall reaction is catalyzed, but when reaction details, e.g. the energy-providing
296 compound, is unresolved. The term “unknown” is used when it is not possible to predict the substrate of the query protein. The term “prediction”
297 is used if a function assignment is based on bioinformatic analyses but not yet on an experimentally characterized homologous protein. The term
298 “special” is used when multiple arguments have to be considered with full details provided in the corresponding section of Suppl. Text S1.
299 Finally, a dash (“-“) is used when isofunctionality does not apply, e.g. when a homologous Gold Standard Protein could not be identified.

3.2 Amino acid metabolism

While most amino acid biosynthesis and degradation pathways can be reliably reconstructed, a few open issues remain, which are discussed below.

(a) The first and last steps of arginine biosynthesis deal with blocking and unblocking of the alpha-amino group of the substrate (glutamate) and a product intermediate (ornithine). As detailed in Suppl. Text S1 Section 2, it is highly likely that glutamate is attached to the gamma-carboxyl group of a carrier protein, and ornithine is released from that carrier protein. This is based on characterized proteins from *Thermus thermophilus* (Horie et al., 2009), *Thermococcus kodakarensis* (Yoshida et al., 2016) and *Sulfolobus acidocaldarius* (Ouchi et al., 2013). The assignment is strongly supported by clustering of the arginine biosynthesis genes. Some of the homologs are bifunctional, being involved in arginine biosynthesis but also in lysine biosynthesis via the prokaryotic variant of the alpha-aminoadipate pathway. This ambiguity is not assumed to occur in haloarchaea, which use the diaminopimelate pathway for Lys biosynthesis (Hochuli et al., 1999) (see Suppl. Text S1 Section 2 for further discussion of this issue).

Expanding the above, we provide full details underlying our reconstruction of arginine and lysine biosynthesis in *Hfx. volcanii* in Table 2.

321

322 Table 2: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 2).** For a description of this table see the
323 legend to Table 1.

(b) Archaea use a different precursor for aromatic amino acid biosynthesis than the classical pathway. This has been resolved for *Methanocaldococcus jannaschii* and for *Methanococcus maripaludis* (White, 2004, Porat et al., 2006). However, the initial steps may differ from those reported for *Methanocaldococcus* in that fructose-1,6-disphosphate rather than 6-deoxy-5-ketofructose might be a substrate (Gulko et al., 2014). Up to now, a clean deletion of the corresponding enzymes and confirmation with in vitro assays has not yet been achieved (for details see Suppl. Text S1 Section 2).

(c) The gene for tryptophanase (*tpa*) is stringently regulated in *Haloferax*, which is the basis for using its promoter in the toolbox for regulated gene expression (Large et al., 2007). The shutdown of this gene avoids tryptophan degradation when supplies are scarce. Tryptophanase cleaves tryptophan into indole, pyruvate and ammonia. The fate of indole is, however, yet unresolved.

(d) A probable histidine utilization cluster exists, based on characterized homologs from *Bacillus subtilis*, but has not yet been experimentally verified.

(e) Among 16 auxotrophic mutants observed in a *Hfx. volcanii* transposon insertion library (Kiljunen et al., 2014), some could grow only in the presence of one (or several) supplied amino acids. In many cases, the affected genes were known to be involved in the corresponding pathway, but the others may lead to novel function assignments. One affected gene resulted in histidine auxotrophy and the product of this gene (HVO_0431) is an interesting candidate. The InterPro domain assignment (HAD family hydrolase) fits to the only remaining pathway gap in histidine biosynthesis (histidinol-phosphatase). In this context it should be noted that the enzyme which catalyzes the preceding reaction (encoded by *hisC*) is part of a highly conserved three-gene operon involved in polar lipid biosynthesis (see below). For details see Suppl. Text S1 Section 2. One affected gene resulted in isoleucine auxotrophy. The product of this gene (HVO_0644) is currently annotated to catalyze two reactions, one being an early step in isoleucine biosynthesis (EC 2.3.1.182), the

other being the first step after leucine biosynthesis branches off from valine biosynthesis (EC 2.3.3.13) (see below, f) (for details see Suppl. Text S1 Section 2).

(f) *Hfx. volcanii* codes for two paralogs with an attributed function as 2-isopropylmalate synthase (EC 2.3.3.13). This is the first reaction specific to leucine biosynthesis, when the pathway branches off valine biosynthesis. One paralog, HVO_0644, is annotated as bifunctional, also catalyzing a chemically similar reaction which is an early step in isoleucine biosynthesis (EC 2.3.1.182). When the gene encoding HVO_0644 is disrupted by transposon integration, cells cannot grow in the absence of isoleucine. It is unclear if the protein is really bifunctional and is really involved in leucine biosynthesis, catalyzing the reaction of EC 2.3.3.13. The other paralog, HVO_1510, belongs to an ortholog set with major problems concerning start codon assignment. The ortholog set from the 16 genomes listed in Suppl. Table S11 were analyzed. When only canonical start codons are considered (ATG, GTG, TTG), then the orthologs from *Haloferax mediterranei*, *Nmn. pharaonis*, *Natronomonas moolapensis* and *Halohasta litchfieldiae* either lack a long highly conserved N-terminal region, or they are disrupted (pseudogenes), being devoid of a potential start codon. The gene from *Hfx. volcanii* has a start codon (GTG) which is consistent to that of *Haloferax gibbonsii* strain LR2-5 (but a GTA in *Hfx. gibbonsii* strain ARA6). In this region, the gene from *Hfx. mediterranei* is closely related but has in-frame stop codons. HVO_1510 is considerably longer than the orthologs from *Haloquadratum walsbyi*, *Haloarcula hispanica*, and *Natrialba magadii*. The first alternative start codon for HVO_1510 codes for Met-93. This protein was proteomically identified in three ArcPP datasets (Schulze et al., 2020), and peptides upstream of Met-93 were identified. This gene might be translated from an atypical start codon, either an in-frame CTG, or an out-of-frame ATG, which would require ribosomal slippage (for details see Suppl. Text S1 Section 2). It is tempting to speculate that translation occurs only when leucine is not available.

3.3 Coenzymes I: cobalamin and heme

The classical heme biosynthesis pathway branches off cobalamin biosynthesis at the level of uroporphyrinogen III. The alternative heme biosynthesis pathway (Bali et al., 2011), which is used by haloarchaea, has an additional common step, the conversion

388 of uroporphyrinogen III to precorrin-2. For heme biosynthesis, precorrin-2 is
 389 converted to siroheme. This pathway has been reconstructed (Siddaramappa et al.,
 390 2012), except for the iron insertion step. For de novo cobalamin biosynthesis,
 391 haloarchaea use the cobalt-early pathway with a cobalt-dependent key reaction being
 392 catalyzed by CbiG (Moore et al., 2013). Several aspects of heme and cobalamin
 393 biosynthesis in haloarchaea are yet unresolved. This is illustrated in Figure 1.
 394

395
 396 **Figure 1. Illustration of the haloarchaeal cobalamin and heme biosynthesis pathways**
 397 **and of the major cobalamin biosynthesis gene cluster.** (A) Biosynthesis pathways. This
 398 illustration is based on the corresponding KEGG map 00860. Small circles represent pathway
 399 intermediates and have their names assigned. Pathway intermediates upstream of Precorrin 2
 400 are not displayed. The circle for sirohydrochlorin is highlighted in red as this is the
 401 branchpoint for heme and cobalamin biosynthesis in haloarchaea. Enzymatic reactions are
 402 shown by arrows, EC numbers being provided in rectangular boxes. Rectangles are colored
 403 when the enzyme has been reconstructed for haloarchaea (blue: heme biosynthesis; dark

yellow: de novo cobalamin biosynthesis; light yellow: late cobaltochelate which may be a salvage reaction). Gene names in green are adopted from KEGG and represent those from bacterial model pathways. Consecutive arrowheads indicate reaction series which are not shown in detail for space reasons. For enzymatic reactions which are considered to be open issues, the *Hfx. volcanii* locus tags are provided. For two pathway gaps (white boxes in the cobalt-early pathway), the type of reaction is indicated (oxidoreductase and ~CH₃, indicating a methylation reaction). The question mark after HVO_B0058 indicates that this protein, currently co-attributed to EC 2.1.1.272, is a candidate for the yet unassigned EC 2.1.1.195 reaction. We note that haloarchaea might use a deviating biosynthesis pathway, e.g. by swapping the methylation and oxidoreductase reactions (not illustrated). (B) The major cobalamin cluster, encoded on megaplasmid pHV3. Arrows are used to indicate the coding strand and are roughly drawn to scale. If assigned, the gene name is provided in addition to the *Hfx. volcanii* locus tag. Locus tags in red indicate genes that are part of the cobalamin cluster.

(a) *Hfx. volcanii* contains two annotated *cblX* genes. For reasons detailed in Suppl.Text S1 Section 3, we predict that one is a cobaltochelate, involved in cobalamin biosynthesis, while the other is a ferrochelate, responsible for conversion of precorrin-2 to siroheme in the alternative heme biosynthesis pathway.

(b) De novo cobalamin biosynthesis has been extensively reconstructed upon curation of the genome annotation (Pfeiffer and Oesterhelt, 2015). All enzymes of the pathway and their associated GSPs are listed in Table 3. Only two pathway gaps remained, and because these are consecutive, it may be possible that the haloarchaeal pathway is non-canonical and proceeds via a novel biosynthetic intermediate. There are only four genes with yet unassigned function in the *Hfx. volcanii* cobalamin gene cluster, and their synteny is well conserved in the majority of haloarchaeal genomes. Thus, these genes are obvious candidates for filling the pathway gaps (for details see Suppl.Text S1 Section 3).

(c) The cobalamin biosynthesis and salvage reactions (those beyond ligand cobyrrinate a,c diamide) involve “adenosylation of the corrin ring, attachment of the aminopropanol arm, and assembly of the nucleotide loop that bridges the lower ligand

dimethylbenzimidazole and the corrin ring” (Rodionov et al., 2003). The enzymes of these branches of cobalamin biosynthesis and their associated GSPs are listed in Table 3. Only two pathway gaps remain open. For one of these, a candidate was proposed upon detailed bioinformatic analysis (Rodionov et al., 2003) (for further details see Suppl.Text S1 Section 3).

(d) Haloarchaea may code for a late cobaltochelatase of the heterotrimeric type. Distantly related GSPs are either cobalt or magnesium chelataes. A late cobaltochelatase is not required for de novo cobalamin biosynthesis via the cobalt-early pathway. We speculate that it may be involved in cobalamin salvage. The chelatase has a mosaic subunit structure as also reported previously (Rodionov et al., 2003) (see Suppl.Text S1 Section 3 for details).

(e) In the alternative heme biosynthesis pathway, siroheme is decarboxylated to 12,18-didecarboxysiroheme, which is attributed to the proteins encoded by *ahbA* and *ahbB*. These are homologous to each other and are organized as two two-domain proteins. It is unclear if AhbA and AhbB function independently or if they form a complex.

3.4 Coenzymes II: coenzyme F420

Even though coenzyme F420 is predominantly associated with methanogenic archaea (Eirich et al., 1979, Jaenchen et al., 1984), it occurs also in bacteria and a small amount of this coenzyme has been detected in non-methanogenic archaea, including halophiles (Lin and White, 1986). The genes required for the biosynthesis of this coenzyme are encoded in haloarchaeal genomes, but the origin and attachment of the phospholactate moiety are not completely resolved (see below). To the best of our knowledge, only a single coenzyme F420 dependent enzymatic reaction has yet been reported for halophilic archaea (de Wit and Eker, 1987). Thus, the importance of this coenzyme in haloarchaeal biology is currently enigmatic and awaits experimental analysis.

(a) The pathway that creates the carbon backbone of this coenzyme has been reconstructed. We list the enzymes with their associated GSPs in Table 4. Coenzyme F420 contains a phospholactate moiety, which was reported to originate from 2-phospho-lactate (Grochowski et al., 2008), but this compound is not well connected to the remainder of metabolism. As summarized in Suppl.Text S1 Section 4, there are various new insights regarding this pathway from recent studies in other prokaryotes (Bashiri et al., 2019, Braga et al., 2019). To the best of our knowledge, the haloarchaeal coenzyme F420 biosynthesis pathway has never been experimentally analyzed.

(b) The prediction of coenzyme F420-specific oxidoreductases in *Mycobacterium* and actinobacteria has been reported (Selengut and Haft, 2010), leading to patterns and domains that are also found in haloarchaea. Several such enzymes are described in Suppl.Text S1 Section 4.

(c) HVO_1937 might be a coenzyme F420-dependent 5,10-methylenetetrahydrofolate reductase (see also below, C1 metabolism, and Suppl.Text S1 Section 4).

489 (d) The precursor for coenzyme F420 may be used by a photo-lyase involved in DNA
490 repair.

492

493 Table 4: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 4)**. For a description of this table see the
494 legend to Table 1.

3.5 Coenzymes III: coenzymes of C1 metabolism: tetrahydrofolate in haloarchaea, methanopterin in methanogens

Halophilic and methanogenic archaea use distinct coenzymes as one-carbon carrier (C1 metabolism): tetrahydrofolate in haloarchaea and methanopterin in methanogens (White, 1988, Maden, 2000). Several characterized methanogenic proteins that act on or with methanopterin have comparably close homologs in haloarchaea (Table 5), which results in misannotation of haloarchaeal proteins (e.g. in SwissProt) as being involved in methanopterin biology. We assume that the haloarchaeal proteins function with the haloarchaeal one-carbon carrier tetrahydrofolate and that this shift in coenzyme specificity is possible due to the structural similarity between methanopterin and tetrahydrofolate (a near-identical core structure consists of a pterin heterocyclic ring linked via a methylene bridge to a phenyl ring; both also have a polyglutamate tail). A detailed review on the many variants of the tetrahydrofolate biosynthetic pathway is available (de Crecy-Lagard, 2014).

(a) Folate biosynthesis requires aminobenzoate. We had proposed candidates for a pathway from chorismate to para-aminobenzoate (Falb et al., 2008, Pfeiffer et al., 2008b) (for details see Suppl.Text S1 Section 5). However, these predictions have not been adopted by KEGG (accessed April 2021) and without experimental confirmation this is unlikely to ever happen.

(b) GTP cyclohydrolase MptA (HVO_2348) catalyzes a reaction in the common part of tetrahydrofolate and methanopterin biosynthesis. The enzymes specific for methanopterin biosynthesis are absent from haloarchaea and thus the assignment of HVO_2348 to the methanopterin biosynthesis pathway in UniProt is invalid (accessed March 2021).

The next common pathway step (EC 3.1.4.56) has been resolved in *M. jannaschii* (MJ0837) but still is a pathway gap in halophilic archaea. MJ0837 is very distantly related to HVO_A0533, which thus is a promising candidate for experimental analysis.

526

527 HVO_2628 shows 30% protein sequence identity to the enzyme catalyzing the first
528 committed step to methanopterin biosynthesis. As detailed in Suppl.Text S1 Section
529 5, we consider it likely that it does not catalyze that reaction.

530

531 (c) Two enzymes that alter the oxidation level of the coenzyme-attached one-carbon
532 compound probably function with tetrahydrofolate, even though their methanogenic
533 homologs function with methanopterin. In contrast to their assignments in KEGG and
534 UniProt (as of March 2021), their probable functions are thus
535 methenyltetrahydrofolate cyclohydrolase (HVO_2573) and 5,10-
536 methylenetetrahydrofolate reductase (HVO_1937) (see Suppl.Text S1 Section 5)

539 Table 5: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 5)**. For a description of this table see the
540 legend to Table 1.

3.6 Coenzymes IV: NAD and FAD (riboflavin)

(a) The energy source for NAD kinase may be ATP or polyphosphate. This is unresolved for the two paralogs of probable NAD kinase (HVO_2363, *nadK1*, HVO_0837, *nadK2*). These show only 25% protein sequence identity to each other (see Suppl. Text S1 Section 6). Polyphosphate was not found in exponentially growing *Hfx. volcanii* cells (Zerulla et al., 2014), so that ATP is the more likely energy source.

(b) HVO_0782 is an enzyme involved in NAD biosynthesis, which is encoded in most haloarchaeal and archaeal genomes. The adjacent gene, HVO_0781, is encoded in nearly all haloarchaeal genomes according to OrthoDB, and with very strong syntenic coupling revealed by SyntTax analysis. Thus, HVO_0781 is a candidate to also be involved in NAD biosynthesis. Characterized homologs to HVO_0781 decompose S-adenosyl-methionine into methionine and adenosine, a reaction that seems wasteful and might not be expected to be highly conserved with respect to existence and gene clustering (see Suppl. Text S1 Section 6).

(c) We describe the reconstruction of riboflavin biosynthesis based on a detailed bioinformatic reconstruction (Rodionova et al., 2017). The enzymes and their associated GSPs are listed in Table 6. Three pathway gaps remain, with candidate genes predicted for two of these (Rodionova et al., 2017) (for details see Suppl. Text S1 Section 6).

3.7 Biosynthesis of membrane lipids, bacterioruberin and menaquinone

Archaeal membrane lipids contain ether-linked isoprenoid side chains (see (Caforio and Driessen, 2017) and references cited therein). The isoprenoid precursor isopentenyl diphosphate is synthesized in haloarchaea by a modified version of the mevalonate pathway (Vannice et al., 2014). Isoprenoid units are then linearly condensed to the C20 compound geranylgeranyl diphosphate. The haloarchaeal core lipid, archaeol, consists of 2,3-sn-glycerol with two C20 isoprenoid side chains attached by ether linkages. In some archaea, especially alkaliphiles, C25 isoprenoids are also found (see e.g. (De and Gambacorta, 1988, Dawson et al., 2012)). Also, a number of distinct headgroups are found in polar lipids (phospholipids) (reviewed in (Caforio and Driessen, 2017)). Even though polar lipids are used as important taxonomic markers (Oren et al., 1997) their biosynthetic pathways are not completely resolved.

Haloarchaea typically have a red color, which is due to carotenoids, mainly the C50 carotenoid bacterioruberin (Oren, 2002, Kushwaha et al., 1975, Yang et al., 2015). For carotenoid biosynthesis, two molecules of geranylgeranyl diphosphate, a C20 compound, are linked head to head to generate phytoene, which is desaturated to lycopene (Falb et al., 2008, Giani et al., 2020). The pathway from lycopene to the C50 compound bacterioruberin has been experimentally characterized (Dummer et al., 2011, Yang et al., 2015).

(a) We assigned HVO_2725 (*idsA1*, paralog of NP_3696A) and HVO_0303 (*idsA2*, paralog of NP_0604A) for the linear isoprenoid condensation reactions resulting in a C20 isoprenoid (EC 2.5.1.10, 2.5.29, short chain isoprenyl diphosphate synthase) (see also Suppl.Text S1 Section 7). Some archaea, mainly haloalkaliphiles, also contain C25 isoprenoid side chains. Geranylgeranyl diphosphate synthase, the enzyme which generates the C25 isoprenoids, has been purified and enzymatically characterized from *Nmn. pharaonis* (Tachibana, 1994), but data that allow the assignment to a specific gene have not been collected. Three paralogous genes from *Nmn. pharaonis* are candidates for this function (NP_0604A, NP_3696A, and NP_4556A). Because NP_0604A and NP_3696A have orthologs in *Hfx. volcanii*, a species devoid of C25

lipids, we assign the synthesis of C25 isoprenoids (geranylgeranyl diphosphate synthase activity) to the third paralog, NP_4556A. UniProt assigns C25 biosynthesis activity to NP_3696A for undescribed reasons (as of April 2021) and KEGG does not make this assignment for any of the three paralogs (as of April 2021). Our assignments are supported by analysis of key residues which determine the length of the isoprenoid chain (Bale et al., 2019). These authors label the cluster containing NP_3696A (WP011323557.1) as “C15/C20” and the cluster containing NP_4556A (WP011323984.1) as “C20->C25->C30?”.

(b) Typical polar lipids in haloarchaea are phosphatidylglycerophosphate methyl ester (PGP-Me) and phosphatidylglycerol (PG), but also phosphatidylglycerosulfate (PGS) (Kates, 1993, Kates et al., 1993, Bale et al., 2019). Other polar lipids are archaetidylserine and its decarboxylation product archaetidylethanolamine, both of which are found in rather low quantities in *Haloferax* (Kellermann et al., 2016). A third group of polar lipids has a headgroup derived from myo-inositol. The biosynthetic pathway of the head groups is only partially resolved. One CDP-archaeol 1-archaetidyltransferase that belongs to a highly conserved three-gene operon may attach either glycerol phosphate or myo-inositol phosphate. In Suppl. Text S1 Section 7 we summarize arguments in favor of each of these candidates, but the true function can only be decided by experimental analysis.

(c) Carotenoid biosynthesis involves the head-to-head condensation of the C20 isoprenoid geranylgeranyl diphosphate to phytoene, which is desaturated to lycopene (Falb et al., 2008, Giani et al., 2020). The *crtB* gene product (e.g. HVO_2524) catalyzes the head-to-head condensation. It is yet uncertain which gene product is responsible for the desaturation of phytoene to lycopene. The further pathway from lycopene to bacterioruberin has been experimentally characterized in *Haloarcula japonica* (Yang et al., 2015). A three gene cluster (*crtD-lyeJ-cruF*) codes for the three enzymes of this pathway. The synteny of this three gene cluster is strongly conserved according to SyntTax analysis. Several genes which are certainly or possibly involved in carotenoid biosynthesis are encoded in the vicinity of this cluster (for details see Suppl. Text S1 Section 7).

632 (d) Halophilic archaea contain menaquinone as a lipid based two electron carrier of
 633 the respiratory chain (Elling et al., 2016, Kellermann et al., 2016). We describe the
 634 reconstruction of the menaquinone biosynthesis pathway (Table 7), with two pathway
 635 gaps remaining open (see Suppl.Text S1 Section 7 for details).

638 Table 7: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 7)**. For a description of this table see the
639 legend to Table 1.

3.8 Issues concerning RNA polymerase, protein translation components and signal peptide degradation

(a) Haloarchaeal RNA polymerase consists of a set of canonical subunits (encoded by *rpoA1A2B1B2DEFHKLNP*). *Hbt. salinarum* and a subset of other haloarchaea contain an additional subunit called epsilon (Leffers et al., 1989, Madon and Zillig, 1983). Purified RNA polymerase containing the epsilon subunit transcribes native templates efficiently, in contrast to RNA polymerase devoid of this subunit (Madon and Zillig, 1983). The biological relevance of this subunit is enigmatic (see Suppl.Text S1 Section 8).

(b) Two distant paralogs are found for haloarchaeal ribosomal protein S10 (uS10) in nearly all haloarchaeal genomes. It is uncertain if both occur in the ribosome, whether they occur together or are mutually exclusive. The latter distribution would result in heterogeneity of the ribosomes. Alternatively, one of the paralogs may exclusively have a non-ribosomal function.

In a subset of archaea, two distant paralogs are found for haloarchaeal ribosomal protein S14 (uS14) (ca 20% of the genomes, e.g. in *Nmn. pharaonis*). For more details see Suppl.Text S1 Section 8.

(c) The ribosomal protein L43e (eL43) shows heterogeneity with respect to the present of C2-C2 type zinc finger motif. This zinc finger is found in L43e from all *Halobacteriales* and all euryarchaeal proteins outside the order *Halobacteria*, but is not found in *Haloferacales* and very rare in *Natrialbales*, . Eukaryotic orthologs (e.g. from rat and yeast) contain this zinc finger and its biological importance has been experimentally shown for the yeast protein (Rivlin et al., 1999) (for details see Suppl.Text S1 Section 8).

(d) Diphthamide is a complex covalent modification of a histidine residue of translation elongation factor α -EF2. The pathway has been reconstructed (Table 8), based on distant homologs (enzymes encoded by *dph2*, *dph5*) and by detailed

671 bioinformatic analysis (enzyme encoded by *dph6*) (de Crecy-Lagard et al., 2012) (for
672 details see Suppl.Text S1 Section 8). These uncertain function assignments await
673 experimental confirmation.

674

675 (e) N-terminal signal sequences target proteins to the secretion machinery.
676 Subsequent to membrane insertion or transmembrane transfer, the signal sequence is
677 cleaved off by signal peptidase. After cleavage, the signal peptide must be degraded
678 to avoid clogging of the membrane. Degradation is catalyzed by signal peptide
679 peptidase. Candidates for this activity have been predicted from two protein families
680 (Ng et al., 2007, Raut et al., 2021) (for details see Suppl.Text S1 Section 8).

683 Table 8: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 8)**. For a description of this table see the
684 legend to Table 1.

3.9 Miscellaneous metabolic enzymes and proteins with other functions

Here, we list a few other enzymatic or non-enzymatic functions for which candidate genes have been assigned, but without experimental validation.

(a) Ketohexokinase from *Haloarcula vallismortis* has been experimentally characterized (Rangaswamy and Altekari, 1994). However, the activity was not assigned to a gene. Detailed bioinformatic analyses have been made (Anderson et al., 2011, Williams et al., 2019) and point to a small set of orthologs represented by Hmuk_2662, the ortholog of HVO_1812 (for further details see Suppl. Text S1 Section 9).

(b) The assignment of fructokinase activity to the *Hht. litchfieldiae* candidate gene halTADL_1913 (UniProt:A0A1H6QYL4) is based on differential proteomic analysis (Williams et al., 2019) (see Suppl. Text S1 Section 9 for details). Very close homologs are rare in haloarchaea. For this protein family (carbohydrate kinase) it is unclear if more distant homologs (with about 50% protein sequence identity) are isofunctional.

(c) A candidate gene for glucoamylase is HVO_1711 for reasons described in Suppl. Text S1 Section 9. The enzyme from *Halorubrum sodomense* has been characterized (Chaga et al., 1993) but the activity was not yet assigned to a gene.

(d) A strong candidate for having glucose-6-phosphate isomerase activity is *Hfx. volcanii* (HVO_1967, *pgi*), based on 36% protein sequence identity to the characterized enzyme from *M. jannaschii* (MJ1605) (Rudolph et al., 2004) (Table 9).

711

712 Table 9: **Proteins with open annotation issues and their Gold Standard Protein homologs (Section 9)**. For a description of this table see the

713 legend to Table 1.

(e) A candidate gene for specifying an enzyme with 2-dehydro-3-deoxy-(phospho)gluconate aldolase activity is *Hbt. salinarum kdgA* (OE_1665R). It is rather closely related (36% protein sequence) to *Hfx. volcanii* HVO_1101 (encoded by *dapA*), which is involved in lysine biosynthesis, a biosynthetic pathway that is absent from *Hbt. salinarum*. The function assignment is based on distant homologs from *Saccharolobus (Sulfolobus) solfataricus* and *Thermoproteus tenax* which have been characterized (Ahmed et al., 2005) (for details see Suppl. Text S1 Section 9).

(f) Haloarchaea may contain an NAD-independent L-lactate dehydrogenase, LudBC (HVO_1692 and HVO_1693). Deletion of this gene pair impairs growth on rhamnose, which is catabolized to pyruvate and lactate (Reinhardt et al., 2019). There is a very distant relationship (for details see Suppl. Text S1 Section 9) to the LldABC subunits of the characterized L-lactate dehydrogenase from *Pseudomonas stutzeri* A1501 (Gao et al., 2015) and to the LutABC proteins from *B. subtilis*, which have been shown to be involved in lactose utilization (Chai et al., 2009).

(g) *Hfx. volcanii* may be able to convert urate to allantoin, using the gene cluster HVO_B0299-HVO_B0302. This could be part of a complete degradation pathway for purines, which, however, has to be considered highly speculative (see Suppl. Text S1 Section 9).

(h) *Hfx. volcanii* may contain an enzyme having a "nickel-pincer cofactor". The biogenesis of this cofactor may be catalyzed by *larBCE* (as detailed in Suppl. Text S1 Section 9).

(i) cyclic diguanylate hydrolysis

Cyclic di-AMP (c-di-AMP) is an important nucleotide signalling molecule in bacteria and archaea. It is generated from two molecules of ATP by diadenylate cyclase (encoded by *dacZ*) and is degraded to pApA by phosphodiesterases (Corrigan and Grundling, 2013). The level of this signalling molecule is strictly controlled (Gundlach et al., 2015, Commichau et al., 2019), thus requiring a sophisticated interplay of cyclase and phosphodiesterase. *DacZ* from *Hfx. volcanii* has been

characterized and it was shown that c-di-AMP levels must be tightly regulated (Braun et al., 2019). The degrading enzyme, however, has not yet been identified in *Haloferax* but candidates have been proposed (Corrigan and Grundling, 2013, He et al., 2020, Yin et al., 2020) (see Suppl. Text S1 Section 9).

(j) homolog to RNaseZ

HVO_2763 is distantly related to RNase Z (HVO_0144, *rnz*). The experimental characterization of HVO_2763 (Fischer et al., 2012) excluded activity as exonuclease but did not reveal its physiological function. Upon transcriptome analysis, the downregulation of several genes was detected. Several of these were uncharacterized at the time of the experiment but have since been shown to be involved in the minor N-glycosylation pathway that was initially detected under low salt conditions (see Suppl. Text S1 Section 9 for further details) .

(k) A pair of genes (*dabAB*) is predicted to function as CO₂ transporter.

HVO_2410 and HVO_2411 probably function as carbon dioxide transporter, based on the identification of such transporters in *Halothiobacillus neapolitanus* (Desmarais et al., 2019). Being a member of the proton-conducting membrane transporter family, this protein may be misannotated as a subunit of the *nuo* or *mrp* complex (see Suppl. Text S1 Section 9 for further details).

4. Conclusion

We describe a large number of cases where protein function cannot be correctly predicted when restricting considerations to computational analyses without taking the biological context into account. An example is the switch from methanopterin to tetrahydrofolate as C1 carrier in haloarchaea. Homologous enzymes, inherited from the common ancestor, have adapted to the new C1 carrier, rather being replaced by non-homologous proteins. Function prediction tools may misannotate haloarchaeal proteins to work with methanopterin. Another example is the *nuo* complex and its misannotation as a type I NADH dehydrogenase. In other cases, even distant sequence similarity may allow a valid function prediction if additional evidence (e.g. from gene

777 neighbourhood analysis or from detailed evaluation of metabolic pathway gaps) is
 778 taken into account. Examples include cobalamin cluster proteins, which probably
 779 close the two residual pathway gaps, and the predicted degradation pathway for
 780 purines. In all these cases, we have presented reasonable hypotheses based on current
 781 knowledge, and in many cases these are so well supported as to be compelling, but to
 782 be certain, experimental data are required. With this overview, we attempt to arouse
 783 the curiosity of colleagues, hoping that they will confirm or disprove our speculations
 784 and thus advance the knowledge about haloarchaeal biology. *Hfx. volcanii* is a model
 785 species for halophilic archaea, and the more complete and correctly its genome is
 786 annotated, the higher will be its value for systems biology analyses (modelling) and
 787 for synthetic biology (metabolic engineering) and biotechnology.

Acknowledgments

We thank all members of the *Haloferax* community for more than a decade of fruitful cooperation and for sharing their deep knowledge about the biology of this model species. We thank our colleagues for kindly reading and providing thoughtful comments on the manuscript before submission: Sonja-Verena Albers, Thorsten Allers, Maria Jose Bonete, Rosana de Castro, Sebastien Ferreira-Cerca, Anita Marchfelder, Mechthild Pohlschroder, Joerg Soppa. We thank Birgit Scharf for insightful discussions on the *Natronomonas* respiratory chain.
