20

21 One sentence summary

22 Through screening a rice diversity panel for variation in shoot architecture, we identified traits corresponding
23 to plant shading potential and their genetic constituents.

24

25 **Author contributions**

26 M.H., R.P. and R.S. designed the experiments, with additional input from K.K., J.T. and H.v.V.; M.H.
 27 performed all experiments, analysed the data, and wrote the article with contributions of all authors; M.M.J.
 28 carried out the haplotype analysis and assisted with statistical data analysis and data visualization; B.S.
 29 provided technical assistance for the genome-wide association studies and performed part of the analysis;
 30 H.v.V. provided assistance for statistical analysis; J.T. performed part of the experiment and measurements;
 31 V.K. contributed to research plan and experiment support at IRRI; R.P. serves as the author responsible for
 32 contact and ensures communication, supervised all experiments, revised the manuscript draft and together with
 33 R.S. conceived the research plan and project design.

 37 14700.RS) in collaboration with The International Rice Research Institute.

38

39 Abstract

40 Rice feeds more than half of the world's human population. In modern rice farming, a major constraint for
 41 productivity is weed proliferation and the ecological impact of herbicide application. Increased weed
 42 competitiveness of commercial rice varieties requires enhanced shade casting to limit growth of shade-
 43 sensitive weeds and the need for herbicide. We aimed to identify traits that enhance rice shading capacity based
 44 on the canopy architecture and the underlying genetic components. We performed a phenotypic screen of a
 45 rice diversity panel comprised of 344 varieties, examining 13 canopy architecture traits linked with shading
 46 capacity in 4-week-old plants. The analysis revealed a vast range of phenotypic variation across the diversity
 47 panel. We used trait correlation and clustering to identify core traits that define shading capacity to be shoot
 48 area, number of leaves, culm and solidity (the compactness of the shoot). To simplify the complex canopy
 49 architecture, these traits were combined into a Shading Rank metric that is indicative of a plant's ability to cast
 50 shade. Genome wide association study (GWAS) revealed genetic loci underlying canopy architecture traits,
 51 out of which five loci were substantially contributing to shading potential. Subsequent haplotype analysis
 52 further explored allelic variation and identified seven haplotypes associated with increased shading.
 53 Identification of traits contributing to shading capacity and underlying allelic variation presented in this study
 54 will serve future genomic assisted breeding programmes. The investigated diversity panel, including widely
 55 grown varieties, shows that there is big potential and genetic resources for improvement of elite breeding lines.
 56 Implementing increased shading in rice breeding will make its farming less dependent on herbicides and
 57 contribute towards more environmentally sustainable agriculture.

58

59 Introduction

60 Rice feeds more than half of the world's population as a staple food (Kennedy and Burlingame, 2003; Wing et
61 al., 2018). In traditional rice farming, seedlings are transplanted into flooded paddy fields. This works as a
62 natural way to prevent weed infestation, since it gives rice seedlings a size advantage in addition to flood-
63 suppressed germination and growth of weeds. This practice is increasingly problematic, both because of the
64 high manual labour input (Kumar and Ladha 2011; Chakraborty et al. 2017) and because global climate change
65 is reducing the availability of fresh water not only for rice farmers but for the global agricultural sector (FAO,
66 2019; Oliver et al., 2019). Traditional rice farming system is transitioning towards direct-seeded rice, where
67 rice seeds are directly sown into the fields. This practice drastically reduces the water requirement and labour
68 input (Chauhan et al., 2017; Farooq et al., 2011; Kumar and Ladha, 2011). Besides all of its advantages, the
69 major constraint for direct-seeded rice is abundant proliferation of weeds (Rao et al. 2017; Xu et al. 2019). In
70 direct-seeded rice practice, rice seedlings are directly competing with weeds as they lose their seedling size
71 advantage. Waterlogging cannot be applied to suppress emerging weeds, as most modern rice cultivars do not
72 germinate under water (Chauhan, 2012; Ghosal et al., 2019; Kretschmar et al., 2015). Currently, weeds are
73 suppressed with herbicides, leading to evolution of herbicide-resistant weeds and ground water pollution. This
74 creates a pressing need for deployment of sustainable weed management options (Chauhan, 2012a; Chauhan
75 and Yadav, 2013; Mennan et al., 2012; Zhao et al., 2006a). One possible solution to this problem is to increase
76 weed-competitiveness of the rice seedling (Rao et al., 2007; Sakamoto et al., 2006; Zhao et al., 2007).

77 Just like their wild ancestors, shade casting crop varieties compete with invading weeds by reducing the weed's
78 access to full sunlight, thereby impeding their growth. However, the traits contributing to shading potential
79 were neglected or even selected against in breeding efforts, since tall plants and droopy leaves are generally
80 considered as undesired, because it makes harvesting more difficult. Here we propose to develop weed-
81 competitive rice varieties, by selecting for an ideotype with faster growth and high shade-casting potential on
82 proximate weeds. Shoot architecture traits that help plants to gain advantage over their neighbours through
83 light competition include: high number of leaves, increased tillering, large projected shoot area, increased
84 planar angle of leaves and tillers (Andrew et al., 2015; Brainard et al., 2005; Mahajan and Chauhan, 2013;
85 Seavers and Wright, 1999; Worthington and Reberg-Horton, 2013). Accelerated vertical growth might provide
86 an additional advantage for outcompeting neighbours, yet plant height has been strongly selected against
87 during green revolution of most cereals, including rice. Indeed, there exists great potential for weed
88 suppression in cereal canopies, as has been shown for wheat, where a rapidly closing wheat crop canopy
89 achieved through higher planting density, depleted weeds from access to light (Weiner et al., 2010).

90 Building on the idea to increase shading for improved weed competitiveness, here we examined the variation
91 in rice shoot architecture, derived the traits that contribute to shading potential, and identified genetic loci
92 associated with shading potential. The shading potential was defined here as high ground cover and early
93 growth vigour. We determined key architectural characteristics of shading potential in the early growth phase.
94 For this, (1) we phenotyped a rice diversity panel of 344 globally distributed varieties where we recorded 13

quantitative traits. Based on these, (2) we determined key architectural characteristics of shading potential in early growth phase. (3) We combined these core traits into one parameter to develop the Shading Rank, where all studied rice varieties were ranked for their shading potential. (4) Genome-wide association study (GWAS) revealed association with five genetic loci for traits contributing to shade potential. The results of this study form a primer to identification of alleles contributing to increased shading and early plant vigour.

100

Results

Shoot architecture variation between rice varieties

In order to establish the variation in shading potential, and resulting increased weed-competitiveness, within the rice diversity panel (Supplemental Table 1) we measured 13 traits on 4-week-old seedlings in the greenhouse (Figure 1, Table 1, Supplemental Table 2).

Substantial variation was observed for all measured traits among the varieties belonging to different subpopulations (Figure 1; Supplemental Table 2). The *indica* subpopulation showed highest dry weight, number of leaves, and number of tillers followed by *aus* subpopulation and *aromatic*, *tropical* and *temperate japonica* ranked lowest in these parameters (Supplemental Table 2). Shoot and hull area were also observed to be higher in *indica* and *aus* subpopulations, intermediate in *aromatic* subpopulation and lowest in *japonicas* and *admixture* subpopulations. *Indica* and *aus* on average develop the most compact shoots (highest solidity), contrasting with the low solidity of *japonicas* and *aromatic*. In plant height, *indica* lines and *temperate japonica* were shortest and *aromatic* subpopulation were tallest. When taking the entire diversity panel of 344 varieties, five traits (shoot area, hull area, solidity, plant height and dry weight) already showed a significant difference between the individual varieties at four weeks after sowing (Supplemental Table 2). When grouped together in subpopulations, all traits showed significant differences between subpopulations (Supplemental Table 2). Overall, it appears that relatively large variation between subpopulations was observed for traits related to area and branchiness related traits, whereas traits related to height showed only little variation between subpopulations. These differences are clearly determined by differences in genetic background since the growth conditions were constant. The high variation observed for traits related to shading potential suggests that the investigated rice diversity panel has sufficient variation to improve shading of the elite-breeding varieties.

123

Correlation of shoot architectural traits

To explore the relationship between individually measured traits, and determine which traits are independent of each other, we performed a Pearson correlation analysis (Figure 2A, Supplemental Figure 1). Shoot area and hull area showed strong positive correlation with shoot dry weight. Leaf and tiller number were highly correlated with dry weight. Height-associated traits, such as plant height, culm height and leaf length, were

129 positively correlated with each other. On the other hand, a negative correlation was found between culm height
130 and number of leaves and tillers. Solidity, leaf angle, tiller angle and droopiness did not exhibit strong
131 correlation with other measured traits.

132 To examine the types of canopy architecture exhibited within rice diversity panel, we performed hierarchical
133 clustering (Figure 2B), resulting in seven trait clusters. The clustering shows how traits are grouped together
134 according to the patterns observed across all rice varieties. Taking the correlation and clustering analyses
135 together, we can determine core groups of traits: area-related (shoot area, hull area, perimeter), branchiness
136 (number of leaves and tillers and dry weight), height-related (plant and culm height and leaf length), solidity,
137 leaf angle, tiller angle and droopiness (Table 2).

138

139 **Defining “shading potential”**

140 The shading potential of a plant determines the effectiveness with which it can cover ground area. The shading
141 potential increases with an increasing number of leaves and tillers (branchiness), the size of the leaf and tiller
142 angles, and the shoot area. Additionally, the shading potential accounts for plant height, as it offers competitive
143 advantage to shading shorter weed plants. Therefore, plants with an increased height, number of leaves and
144 wider angles are considered more vigorous, and thus likely to outcompete weeds for sunlight by casting more
145 shade. With the aim of finding the ideal plant with highest shading potential for effective weed competition,
146 we need to determine varieties with high values for core traits. The distribution of the different varieties with
147 respect to the core trait groups: area, branchiness, height and solidity are shown in Figure 3, together with top
148 images of representative varieties.

149 To quantify shading potential, we ranked varieties for the sum of the core traits contributing to shading potential
150 (projected shoot area, number of leaves, solidity, culm height, leaf angle, tiller angle and leaf droopiness, bold
151 in Table 2). To account for the differences in measured units and unit ranges, for each trait, the values were
152 rescaled to a range from 0 to 100, whilst keeping the relative differences of trait-values between different
153 varieties unchanged and these relative differences of trait values are also reflected in the sum of the normalized
154 trait values. Varieties then were ranked according to their sum of normalized trait values, from 344 (highest)
155 to 1 (lowest), resulting in the Shading Rank (for detailed information see Methods section - Data processing
156 and statistical analysis).

157 The Shading Rank gives a quantitative measure of the shading potential for a certain variety and indicates
158 where a specific variety ranks with respect to the entire diversity panel (Supplemental Table 3). Although this
159 ranking allows insight into the distribution of shading potential and the identification of expected strong and
160 weak shaders, a limitation of this ranking is that it applies only within the diversity panel tested. Shoot size is
161 one of the major factors contributing to overall shading potential. Since the diversity panel was evaluated 28
162 days after sowing, the large shoot size of high-ranking varieties also indicates faster growth and seedling
163 vigour. The varieties with the highest Shading Rank were Shim Balte, Sze Guen Zim, Paraiba Chines Nova, P

164 737, Shirkati and Sabharaj, while varieties with lowest Shading Rank were Luk Takhar, Guineandao, Bul Zo
165 and Shirogane. From the 25 highest ranking varieties, 14 belong to the *indica subpopulation* and eight to *aus*.
166 Low scoring varieties in terms of shading potential include widely-grown varieties such as IR 64 and
167 Nipponbare, ranking 74th and 73rd respectively (Table 3, Figure 3). This suggests that some of the current elite
168 rice varieties could have a rather poor shading potential, and through breeding with varieties from *indica* and
169 *aus* subpopulations, the shading potential and weed-competitiveness can possibly be increased.

170 Interestingly, none of the top-ranking varieties showed the highest values for all core shading traits (Figure 3).
171 For example, Sze Guen Zim ranks highest for shoot area and number of leaves, but is one of the lower-ranking
172 varieties for culm height. The accession with the highest Shade Ranking (344), Shim Balte has a very high
173 number of leaves and solidity, but has a close to average culm height. Mudgo reaches a rank of 340, despite
174 its relatively low number of leaves and solidity. Della, a variety with a low rank of 49, ranks low for all traits
175 except for culm height. Luk Takhar is at the bottom end of the ranking and shows low values for all core traits.
176 The core traits that determine shading potential: shoot area, number of leaves, solidity and culm height are
177 only weakly correlated (Figure 2, Figure 3), illustrating the diverse strategies to reach high shading potential.
178 It is therefore important to include all of the four core traits, in addition to the angle related traits, for a
179 comprehensive evaluation of shading potential.

180

181 Predicted competitive varieties are casting more shade

182 To validate our Shading Rank and assess functional shading capacity, we grew varieties with varying Shading
183 Rank and evaluated them for canopy shading. We selected two of the predicted competitive (Shim Balte with
184 a Shading Rank of 344 and Mudgo ranking 330) and two predicted non-competitive rice varieties (Luk Takhar
185 ranking 1 and Della ranking 49) (Figure 3, Table 3). By measuring the light quantity under the canopies of
186 selected varieties (Supplemental Table 4), we indeed observed strong shading by varieties with a high Shading
187 Rank (Shim Balte and Mudgo) and low shading by varieties with a low Shading Rank (Luk Takhar and Della).
188 This result validates our Shading Rank, at least for the varieties tested and the selection of shoot architecture
189 traits to effectively predict shade casting.

190 SNPs associated with seedling establishment and shoot architectural traits

191 The high phenotypic variability found in the studied diversity panel (Supplemental Table 5), together with the
192 high genetic variation (Wang et al., 2018b) provides a strong basis for a GWAS. We observed high narrow-
193 sense heritability for all measured traits (Supplemental Table 6). We investigated the genomic trait associations
194 on two different SNP sets, both with two different software packages (lme4QTL (Ziyatdinov et al., 2018) and
195 Genomic Association and Prediction Integrated Tool (GAPIT) (Tang et al., 2016; Wang et al., 2018c), see
196 methods for detailed description). The total list of p-values for SNPs association across all measured traits can
197 be found at <https://doi.org/10.5281/zenodo.4730232> (Supplemental Data 3).

198 Three genomic regions were associated with plant height located on chromosome 3, 5 and 6 (Figure 5). The
199 peak on chromosome 3 was also detected for other height related traits: culm height and leaf length
200 (Supplemental Data 4). Overall, the associations with culm height showed lower LOD scores (Supplemental
201 Data 4). The results for tiller angle and droopiness reveal strong associations with SNPs on chromosome 1 and
202 chromosomes 1 and 10, respectively (Supplemental Data 4). Despite solidity being a very complex and likely
203 a poly-genic trait, the analysis revealed a strong association with 14 SNPs in the locus on chromosome 3
204 (Figure 5). The associations between leaf or tiller number, found for SNPs on chromosomes 11 and 12, were
205 shared between these two traits (Supplemental Data 4). These two loci were also found for dry weight. This
206 suggests that the genetic components underlying formation of new leaves and tillers might have a common
207 genetic constituent, consistent with high correlation in their phenotypes (Figure 2). The analysis for dry weight
208 revealed significant associations on chromosomes 3, 7 and 12, overlapping with the associations found for
209 shoot area (Figure 5). When taking together shading potential as the sum of all core traits, a GWAS on this
210 composite trait yielded a rather random pattern of SNP associations (Supplement Figure 4). This further
211 highlights our earlier findings (Figure 4), that shading can be achieved through various strategies and shading
212 potential, as such, is genetically a highly complex trait. Therefore, genetic mapping of shoot architecture
213 components that contribute to shading capacity is much more effective approach in identifying genetic
214 components that contribute to shading and potential weed competitiveness.

215

216 Identification of alleles associated with increased shading potential

217 The genomic regions that consisted of multiple SNPs above the Bonferroni threshold within the calculated
218 local average LD (Table 5) were investigated in more detail. Since the traits related to the canopy shading
219 potential are the primary focus of this work, we prioritized the loci associated with culm height, shoot area,
220 solidity and dry weight. Locus 4 of shoot area overlaps with locus 5 detected for dry weight (Figure 5, Table
221 5) and was therefore taken together in the follow up analysis. In total we determined five loci to be followed
222 up with a haplotype analysis to identify specific alleles which could contribute to shading potential. By
223 grouping varieties according to SNPs within one coding region, and examining the differences between
224 identified haplotypes, we identified allelic variation associated with high shading potential (Figure 6, Table 6).

The haplotypes of two coding regions in locus 1 (Figure 6 A- B), associated with solidity, were observed to have significantly lower solidity than the most abundant haplotype identified for the respective coding regions. These are annotated as Os03g0845000 (Pirin-like protein) and Os03g0845700 (similar to RPB17 fragment). Haplotypes of two coding regions in locus 2 (Figure 6 C-D), associated with plant height, Os05g0420600 (Cytochrome C) and Os05g0420900 (conserved hypothetical protein), contained taller plants than the most abundant haplotype. In locus 4, associated with shoot area and dry weight, we found that only one gene (Os07g0623200, ATPase and heavy metal transporter protein) showed clear separation across the haplotypes, where all the non-reference haplotypes showed higher shading potential, indicated by higher shoot area and dry weight (Figure 6 E-F). For locus 6, associated with dry weight, we found only one gene Os11g0216000 encoding Pyruvate kinase family protein, we found that the second most abundant haplotype was associated with increased shading due to higher dry weight of varieties that were sharing this specific combination of SNPs.

237

238 Discussion

We studied phenotypic and genetic variation in rice shoot architecture to identify traits and their underlying genetic loci that contribute to canopy shading. We investigated variability across a natural rice diversity panel in shoot architecture at the early vegetative stage. The traits investigated here encompass both early vigour and shade casting through shoot architecture, which are hypothesized to contribute to weed suppression in rice fields. Traits related to shoot architecture, such as leaf angle or droopiness, are of special interest as they do not require substantial resource investment while creating more optimal 3D distribution of the shoot biomass for an increased shading potential. Other traits, such as leaf area, number of leaves or shoot biomass, likely require considerable resource investments and are typically associated with growth vigour i.e. rapid seedling establishment.

In our screen for variation in shoot architecture traits we found significant differences between subpopulations, where varieties with an *indica* background have highest shading potential and *temperate japonica* the least. We found *admixed*, *tropical japonica* and *aus* subpopulations to typically range between *temperate japonica* and *indica*. This pattern could be found in the majority of the measured traits and is in line with the phylogenetic relatedness of the different subpopulations (Eizenga et al., 2014; Liakat Ali et al., 2011; McCouch et al., 2016; Zhao et al., 2011). This indicates that phylogenetic relatedness is an important component that determines phenotypic variation in shoot architecture and shading potential.

255

256 Identification of core shading traits through correlation analysis

In order to summarize the information contained in all the investigated traits into one parameter indicative for the shading potential, we performed an extensive correlation analysis. By assessing the correlation between

individual traits, we identified how all measured traits are related to one another and identified core traits that capture the observed variance (Figure 2). We identified groups of traits related to branchiness (number of leaves and tillers) and height (plant height, culm height and leaf length). The correlations between traits encapsulated within a trait group simply underlines the natural growth pattern; the more tillers a plant has, the more leaves it will have since each tiller will develop a certain number of leaves. Strong correlation was previously observed between tiller formation and relative growth rate (Dingkuhn et al., 2001). Likewise, in our study number of leaves and leaf area were positively correlated with shoot dry weight (Figure 2, Supplemental Figure 1). This well-established relationship (Caton et al., 2003; Dingkuhn et al., 2001; Poorter et al., 2012) can be explained due to a larger shoot area providing higher capacity for photosynthesis and thereby leading to higher overall growth rate (Caton et al., 2003). Not all traits showed expected correlations. It could for example be assumed that an increased inclination angle of the leaf blade would make a leaf droopier. In fact, leaf angle appeared to be unrelated to leaf droopiness, whereas leaf length appeared to be positively correlated with droopiness. While solidity is the ratio of shoot area and hull area, it is only weakly correlated with shoot area (Figure 2, Supplemental Figure 1). This suggests that shoot solidity is independent of how large its total shoot area, leaf number or dry weight are. Since solidity indicates the uniformity of the plant's ability to shade its circumference, it is a valuable trait for shading capacity analysis. Inverse correlations were found between branchiness (number of leaves and tillers) and height traits. This trade-off between height and branching is well-documented as apical dominance where height growth of the main shoot is promoted at the expense of branching (Roig-Villanova and Martínez-García, 2016; Teichmann and Muhr, 2015). Summarizing, the trends observed within this study are in line with earlier observations, whereas we identify new, informative trait groups that contribute independently to the shading potential of rice plants.

280

281 **Shading rank as a measure for shading potential**

Shading potential can be defined in two-dimensional measures, such as ground cover or projected shoot area, or including a third dimension, where plant height is considered as space resource utilization (Zhang et al., 2019). We hypothesized that not only projected shoot area, but also solidity and height of the shoot are crucial for shading potential. For example, a large projected shoot area with low solidity would still leave many open spaces within a single plant's sphere for light penetration where weeds can proliferate. Or the reverse, a very solid projected shoot area of one plant that does not extend very far, is likely to leave open spaces between crop plants where weeds could grow. It is, therefore, clear that an optimal combination of shoot architecture traits is needed for maximal shading and weed suppression (Figure 3, Table 3). Architecture traits that are associated with weed-competitiveness include leaf area, ground cover, specific leaf area, leaf area index, leaf angle, droopiness, tillering capacity and plant height (Caton et al., 2003; Dingkuhn et al., 2001; Haefele et al., 2004; Mahajan and Chauhan, 2013; Mennan et al., 2012; Namuco et al., 2009; Rao et al., 2007; Worthington and Reberg-Horton, 2013; Zhao et al., 2006b, 2007). In addition, plant biomass and early vigour are advantageous for competition against weeds (Haefele et al., 2004; Mahajan and Chauhan, 2013; Namuco et

al., 2009; Worthington and Reberg-Horton, 2013; Zhao et al., 2006a), but these are not specific architecture traits.

To predict which components best describe a plant's shading potential, we categorized the different traits into core groups of similarly behaving traits. We developed the Shading Rank, as a parameter that combines branchiness, solidity and height and leaf and tiller angles and droopiness. The varieties with highest shading potential belong to the *indica* and *aus* subpopulation, which have also been found in earlier studies to have higher yield and less weed biomass in weedy fields compared to *japonicas* (Zhao et al., 2006b). We propose that varieties that have a high Shading Rank, are likely the most weed-competitive varieties, whereas those that rank low are likely to be weak competitors. Indeed, our experiment proved that canopies of high-ranking varieties allow significantly less light penetration than low ranking ones (Figure 4). Interestingly, none of the investigated varieties resembled the full ideotype of a strongly shading plant according to the traits we examined (Figure 3), indicating there is substantial room for improvement. Early seedling vigour is particularly important for weed-competition during the critical period of weed control and some of high ranking varieties, such as Shim Balte, Paung Malaung and Sabharaj are also known by breeders for their early vigour. Increased shading ability is intrinsic to early vigour since it follows to some extent from large size. However, the Shading Rank proposed here is more comprehensive to additional traits such as solidity and plant architecture that may involve less resource investment than vigour traits. With this improved way of ranking a plant's shading capacity, our study exemplifies a new method of selection for high-shading varieties and genetic loci associated with high-shade canopy architecture.

314

315 Elucidating the genetic components of shading potential

316 *Architecture*

The SNP dataset from the rice diversity panel (Eizenga et al., 2014) was combined with the observed phenotypic variation to identify putative genetic loci underlying high shading potential. This variation (Figure 1, Supplemental Table 5) together with a high trait heritability (Supplemental Table 6) provides a strong basis for GWAS. Plant height and leaf length were associated with loci on chromosomes 5 and 6. The locus on chromosome 5 harbours two genes encoding Cytochrome C and a conserved hypothetical protein. The haplotype analysis revealed one allele for both genes that was associated with a highly significant increase in plant height. (Figure 4). The locus on chromosome 6 encodes the *Heading Date (Hd1)* locus that was also previously associated with plant height in vegetative rice plants (Zhang et al., 2012; Yang et al., 2014). Subedi et al. (2019) performed a GWAS on plant height at plant maturity and found peaks on chromosome 1 and 11, which could indicate that at different developmental stages plant height is determined by different genomic regions. However, Subedi et al (2019) used a specifically constructed genetic population stemming from six parents and this could explain why very different loci were identified. Interestingly, haplotypes associated with high culm height exhibit low plant height and vice versa (Supplemental Data 7). Haplotypes associated with high plant height are typically showing longer leaf length (Supplemental Data 7). While all the height related

331 traits were highly correlated at phenotypic level (Figure 2), the lack of common loci for all the traits
332 (Supplemental Data 4), and opposite trends within the haplotype groups (Supplemental Data 7) suggest that
333 the three components of plant height are regulated independently at the genetic level.

334 We also report unique loci specific for solidity and for height related traits. We revealed one strong locus, with
335 several significant SNP associations, on chromosome 3 for solidity (Figure 5). We propose that solidity, as
336 mentioned previously, is an important shoot trait to take into consideration for weed-competitiveness, since
337 high crop plant solidity likely indicates low potential for weeds to proliferate within the sphere of influence of
338 crop individuals. It is surprising to find a single locus, uniquely associated with this complex trait. However,
339 when we grouped varieties into haplotype groups for two coding regions (Os03g0845000 and Os03g0845700,
340 Figure 6 A – B), encoding a Pirin-like protein and an RPB17 (Fragment) within this locus, the phenotype of
341 the haplotype groups appeared to differ not just in solidity, but also shoot area, dry weight and leaf number
342 (Figure 6 A-B, Supplemental Data 7).

343 In this analysis, we identified new genetic components of shading potential based on shoot architecture, and
344 the alleles that might contribute to increased shade casting ability.

345 *Vigour*

346 Vigour-related traits (i.e., dry weight, shoot area, number of leaves) are all strongly correlated and share
347 associated loci on chromosome 7, 11 and 12 (Figure 5, Supplemental Data 4). The locus on chromosome 11
348 was also reported by (Yang et al., 2014) for dry weight and fresh weight at the late tillering stage, which is
349 comparable to the developmental stage studied here. A closer look at the locus found for dry weight on
350 chromosome 11 revealed only one gene is located within the linkage disequilibrium of associated SNPs.
351 Interestingly, the haplotype analysis for SNPs within Os11g021600, encoding a Pyruvate kinase family protein,
352 revealed significant difference in dry weight between the two haplotype groups (Figure 6 G). The significant
353 differences were also observed for shoot area and number of leaves and tillers. As only one gene was located
354 within this locus and one specific haplotype was related with high biomass, this locus is a promising candidate
355 for follow-up studies and promising to be included in breeding programmes. The locus on chromosome 7
356 associated with shoot area and dry weight (Figure 6 E and F), harbours two genes, where we found that the
357 haplotypes were associated with an increased shoot area and dry weight but also increased number of leaves
358 and tillers. QTLs for height at 7 and 14 days after sowing and fresh weight, in a study that involved exclusively
359 *temperate japonica* genotypes (Cordero-Lara et al., 2016) were entirely non-overlapping with the loci
360 identified here for these traits. This is most likely because of the different genetic make-up of the populations
361 used, which inevitably leads to variation. Even though the GWAS results for number of leaves and dry weight
362 revealed different genetic associations for each of these traits, the identified haplotypes affected both these
363 traits in a similar way. The haplotypes associated with high projected shoot area also showed increased
364 branchiness and dry weight (Supplemental Data 4). This might suggest that by selecting for a genetic locus
365 associated with branchiness, the other traits contributing to shading potential might also be affected. This

relationship is to be further studied in future reverse-genetic studies that could explore the role of identified candidate loci in increased shading potential as well as weed-competitiveness.

It should be kept in mind that rice is known to be a highly plastic species and we have performed our experiments under stable conditions in a controlled environment. In order to further translate our findings, and implement them in breeding programmes, it will be relevant to factor in architectural plasticity under field conditions. One obvious factor affecting architecture would be planting density and the associated changes in light composition and availability. Another so far neglected aspect of weed-competitiveness would be the root systems, for which the rapidly evolving high throughput phenotyping methods are a major opportunity to resolve comparable questions as done here for shoot architecture. We conclude that breeding for specific vigour traits will likely have additional beneficial effects, as indicated by the haplotype studies. Vigour from root growth can then be an added layer at a later step towards field-grown, weed-competitive varieties that can be farmed in a sustainable manner.

Conclusion

This study explored diversity in shoot architecture of rice seedlings, identified traits contributing to canopy shading potential and identified the putative genetic components related to canopy shading. The traits contributing to a high Shading Rank, and therefore a proposed increased weed-competitiveness, are also intrinsically relevant for seedling vigour. Shoot area, number of leaves and plant height contribute strongly to early vigour and are therefore imperative target traits for weed-competitiveness. We also highlight additional shoot architecture traits, such as solidity and leaf angles, that contribute to increased shading potential and are therefore desirable traits for weed-competitiveness (Figure 2). Indeed, we confirmed that light extinction is significantly stronger under canopies of varieties predicted to have high shading potential and therefore likely being more weed-competitive.

We identified 26 significant marker-trait associations including five novel loci related to canopy shading traits, and the haplotypes corresponding to high-shading potential. Phenotypic investigations carried out in previous studies focused on adult plants and yield traits. This is also reflected in the breeding programme over the last decades, which aimed for high yielding dwarf varieties. Many widely cultivated varieties, such as IR 64 and Nipponbare, showed low Shading Ranks in our analyses, and the most abundant haplotypes, with only few exceptions, were often the ones with lowest shade casting. Our study indicates a clear potential for improvement towards sustainable weed suppression in the current breeding programmes, and that some of the newly studied traits here could be introduced into future breeding programmes.

Summarizing, the acquired knowledge of relevant traits, together with the information about their underlying genomic regions and haplotypes described here can serve as a basis for future reverse-genetic studies and genome-assisted breeding programmes that will contribute to making rice farming more sustainable and help to improve yield in dry, direct-seeded rice.

401 **Material and methods**

402

403 **Plant material**

404 344 Asian rice (*O. sativa*) cultivars were used out of an established rice diversity panel (Rice diversity panel
405 1; RDP1 (Eizenga et al., 2014)). In addition, one African rice variety (*O. glaberrima*) TOG7192 was also
406 included. The RDP1 is a collection of purified, homozygous rice varieties spread over 82 countries all over the
407 world. The panel includes landraces and elite rice cultivars from five subpopulations: *indica* and *aus* belonging
408 to the Indica varietal group and *tropical japonica*, *temperate japonica* and *aromatic* which comprise the
409 Japonica varietal group, in addition to the *admixture* group, (Liakat Ali et al., 2011; Zhao et al., 2011). The full
410 panel and detailed information (accession name, accession ID, subpopulation and country of origin) can be
411 found in the Supplemental Table 1.

412 **Growth conditions**

413 Rice plants were grown in the screen-house facilities of the International Rice Research Institute (IRRI) in The
414 Philippines, during October 2017 – April 2018. Temperatures ranged from 37 °C during the day to 27 °C during
415 the night, with a relative humidity of 75 % and 80 %, respectively and a photoperiod ranging from 11 to 12
416 hours. Four temporally separated replications were carried out, with three plants per variety within each
417 replicated experiment. Plants were grown in a randomized block design in single pots with a 30 cm x 30 cm
418 distance between seedlings. In the first experiment, seeds received from the gene bank at IRRI were exposed
419 to 40 °C for up to 5 days, to break dormancy, followed by 24 h at 21 °C. For germination, seeds were put in
420 Petri dishes (12 per variety) on wet filter paper and incubated at 32 °C for 24 h. Seeds were planted directly
421 on the soil, following the direct-seeded rice method: 4 seeds were placed per pot (diameter of 16 cm and 13
422 cm high, without drainage holes on the bottom) filled with sterilized clay-loam field soil mixed with complete
423 fertilizer (NPK fertilizer with 46 / 18 / 60 g per kg soil). The seeds were sown at a depth of x-cm and then
424 covered with a thin layer of soil. From planting onwards, soil was kept moist. At 7 days after sowing (DAS),
425 surplus seedlings were removed to retain only 1 seedling per pot. At 14 DAS, fertilizer was added, with 50%
426 of N of concentration off first application. From 15 DAS until the end of the experiment, watering was done
427 to keep a layer of water on the soil and the plants under water-logged conditions.

428 **Phenotyping**

429 Plants were measured by hand at 28 DAS for the following traits: number of leaves, number of tillers, total
430 plant height, culm height, and length of longest leaf. Plants were photographed from the top and side using 2
431 digital cameras in a fixed imaging set-up at 21 and 28 DAS. At the last time point, a scan of the blade of the
432 longest leaf was taken and the whole shoot was harvested for analysis of dry weight upon 48 h of drying at
433 70 °C (IRRI, 2013; Caton et al., 2003). In Table 1, each trait, their abbreviations and evaluation methods are
434 described. The raw data for each replicate can be accessed at <https://doi.org/10.5281/zenodo.4730232>
435 (Supplemental Data 1).

436 Data processing and statistical analysis

437 In order to extract traits from RGB images, an automatised image analysis pipeline was established using the
 438 open source, python based PlantCV software (PlantCV version 3.7) (Fahlgren et al., 2015; Gehan et al., 2017).
 439 We made optimisations to the script for detection of monocots, to enable the extraction of values for shoot
 440 area, hull area and perimeter. The python script describing the developed pipeline can be accessed at
 441 <https://plantcv.readthedocs.io/en/stable/> and the adapted Jupiter notebook used for processing all the images
 442 at <https://doi.org/10.5281/zenodo.4730232> (Supplemental Data 2). The measurements of tiller angle, leaf angle
 443 and leaf erectness, were done using the free ImageJ software (<https://imagej.nih.gov/ij/>). Tiller angles were
 444 taken between the two outermost tillers and the culm, respectively. The leaf angles were taken between the
 445 second and third youngest leaf and the culm, respectively. The leaf droopiness was measured on the same
 446 leaves as the interception angle of two tangents aligned to the initiation and the tip of the leaf blade.

447 The values of the first replicate were excluded for 62 varieties as their position within the greenhouse was
 448 more shaded. These positions were excluded from further experimental replication, to ensure equal light
 449 conditions for all studied plants. Prior to statistical analysis, the raw data was curated for outliers (using
 450 $1.5 \times \text{IQR}$ away from the mean) and mean was calculated out of the four replicates, with two biological
 451 replicates each. Statistical analysis such as ANOVA, Pearson Correlation and Hierarchical Clustering were
 452 performed using R (R Version: 3.6.1-1bionic; R Core Team, 2020) and the online tool MVapp
 453 <https://mvapp.kaust.edu.sa> (Julkowska et al., 2019). The Pearson Correlation coefficients between traits were
 454 calculated using raw data. For Hierarchical Clustering traits and individual samples were clustered using
 455 ward.D2 method. The values of individual traits were normalized per trait using z-Fisher transformation and
 456 scaled prior to clustering. Based on the correlation and clustering analysis, a subset of phenotypic traits, was
 457 defined as the core traits. The core traits were shoot area, leaf number, solidity, culm height, leaf angle, tiller
 458 angle and leaf droopiness. Then we calculated the Shading Rank as follows:

459 First, we normalized the trait values t_{variety}^n

$$460 \quad t_{\text{variety}}^n = \frac{t_{\text{variety}} - \min(t_{\text{variety}})}{\max(t_{\text{variety}}) - \min(t_{\text{variety}})} \times 100$$

461 where t_{variety} is the value of a certain trait measured for a certain plant in the investigated population and min
 462 and max are the minimum and maximum values of the measured trait in the whole population, with the
 463 normalized values ranging from 0 to 100.

464 Next, we calculated the Shading Score for each variety SS_{variety}

465 $SS_{\text{variety}} = \sum_{\text{core traits}} t_{\text{variety}}^n$ where $\sum$ is calculated as the sum only from the normalized values of the core
 466 traits. From this, we get the Shading Rank (SR), which is the rank given to each variety according to its SS,
 467 ordering the varieties from 1 (lowest) to 344 (highest). The list of 344 varieties with their normalized core trait
 468 values, the sum of normalized core trait values and their Shading Rank can be found in Supplemental Table 3.

469 Canopy shading experiment

470 Rice were grown in the greenhouse facilities of Utrecht University, in The Netherlands, in February 2021.
 471 Temperatures were set to 29 °C during the day and 25 °C during the night and a photoperiod from 8 am to 8
 472 pm, with a minimal light intensity of 400 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and artificial light (Valoya, Model Rx400 500mA 5730,
 473 Spectrum AP673L) switching on if sunlight flux rate dropped below 400 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Automatic watering kept
 474 soil in pots saturated. The selected *O. sativa* varieties were Shim Balte, Mudgo, Della and Luk Takhar, with
 475 Shading Ranks of 344, 330, 49 and 1, respectively. Germination protocol was followed as described above.
 476 Four plants were grown per pot, in each of the corners of a square pot (10 x 10 x 11 cm) in a substrate mix of
 477 black soil, vermiculite and sand in a ratio of 5 : 3 : 2 together with 6 g Osmocote and 1 l Yoshida nutrient
 478 solution per kg substrate. Pots were arranged at a distance of 10 cm in mixed plots. The experiment units (the
 479 eight plants that were measured) were surrounded by bordering plants to avoid border effects on the
 480 experimental units. Light intensity (photosynthetic active radiation (PAR) of 400-700 nm waveband) was
 481 measured at the ground level between rice plants (with six measurements in each of the three replicates) and
 482 above the plants for reference at the same time to calculate light extinction. PAR values can be found in
 483 Supplemental Table 4.

484 Phenotype data for GWAS

485 For the GWAS analyses, the mean values of all phenotypes were included, only *O. glaberrima* TOG7192 was
 486 excluded since it does not belong to the *O. sativa* species. We tested for the normal distribution across the
 487 recorded traits prior to running the GWAS. The list for all 344 varieties with 13 shoot trait values (as the mean
 488 value out of eight replicates, for raw data see Supplemental Data 1) which were used as input for GWAS can
 489 be found in Supplemental Table 5.

490 Genotype data

491 For the genotype data we have used two data sets publicly available at <http://ricediversity.org/data/index.cfm>
 492 [tools/](#). As a second dataset, we used the newer version of genomic data imputed HDRA with 4.8 M SNPs, from
 493 3,010 *O. sativa* varieties assembling the established Rice Reference Panel by merging the high-density rice
 494 array with 700 K SNPs from in total 1,568 *O. sativa* varieties including RDP1 (rice diversity panel 1), RDP2
 495 and NIAS (national institute of agrobiological sciences) from (McCouch et al., 2016) and 3000 Rice Genomes
 496 data sets (D. R. Wang et al., 2018). The data was curated by filtering for unique SNPs, 90% call rate (90%
 497 minimum count) and minor allele frequency $\geq 5\%$. We used the SNP data that adhere to the filtering criteria
 498 for 344 varieties that were included in the phenotypic screen, which resulted in total of 1.7 M SNPs remained
 499 as an input for the GWAS. As an average genome-wide linkage disequilibrium (LD) decay in rice we used
 500 previously calculated values (Zhao et al. 2011; Huang et al. 2010). LD is calculated by measuring the pairwise
 501 SNP LD among the common SNPs (with MAF > 0.05) using r^2 , the correlation in frequency among pairs of
 502 alleles across a pair of markers, using the software PLINK (<http://zzz.bwh.harvard.edu/plink/>).

503 **Genome wide association study (GWAS)**

504 We used two different software packages to perform the GWAS. The first is an R package (R version 3.6.1) of
 505 Genomic Association and Prediction Integrated Tool (GAPIT) (Tang et al., 2016; Wang et al., 2018c). We
 506 employed a mixed linear model (MLM) (Yu et al., 2006) with the optimal number of Principal Components
 507 based on the calculated Bayesian information criterion (BIC) for each trait, including as coefficients a kinship
 508 matrix (K-matrix), based on clustering analysis to account for genetic relationship between individuals,
 509 together with the population structure (Q-matrix). The Manhattan plots for GWAS using the GAPIT can be
 510 found in Supplemental Data 5, for shoot area, hull area, perimeter, plant height, culm height, leaf length,
 511 solidity, number of leaves, number of tillers, dry weight, droopiness, leaf angle, tiller angle and the Sum of
 512 normalized traits. Shown are SNPs with MAF > 0.05, with the negative logarithmic p-values on the y-axis, for
 513 1.7 M SNPs across the 12 rice chromosomes along the x-axis. The second software package is lme4QTL
 514 (Ziyatdinov et al., 2018). We performed GWAS as described in the paper, taking population structure into
 515 account by using a kinship matrix. This kinship matrix was calculated using the cov() function in R 3.6
 516 (Supplemental Figure 2). The decomposition matrix to correct for population structure was made by following
 517 the lme4QTL protocol. It uses the relmatLmer(), varcov() and decompose_varcov() functions in order. The
 518 obtained decomposition matrix, together with the traits and binary SNP matrix is then used in the matlm()
 519 function to calculate the significance and effect per SNP. The full list of detected significant SNP associations
 520 can be accessed at <https://doi.org/10.5281/zenodo.4730232> (Supplemental Data 3). As a confirmation for the
 521 reliability of SNP trait associations, we correlated the results of the two methods applied here (GAPIT and
 522 lme4QTL). We do not expect an exact overlap, as there is a small difference in how the kinship matrix is
 523 calculated and GAPIT uses MLM, whereas lme4QTL does not. The narrow sense heritability (h^2) of the
 524 analysed traits was calculated with GAPIT (Supplemental Table 6). To set the significance threshold the rather
 525 conservative Bonferroni correction was applied, calculated by the $-\log^{10}(\text{p-value of } 0.05/\Sigma\text{SNPs})$, which
 526 corresponds to $-\log_{10}(0.05/1.700.000) = -7.53$ for the imputed HDRA data set. To examine the GWAS model
 527 performance and estimate possible model overfitting, QQ plots were generated (Supplemental Data 6).

528 **Post-GWAS analysis**

529 For all follow-up analysis the output of the GWAS on the raw, untransformed phenotype data was used.

530 **Locus definition:** We determined loci to be of interest, if there are several significantly associated SNPs found
 531 in close proximity. Single SNPs passing the threshold were neglected, because whole-genome sequencing data
 532 provides enough markers in each linkage disequilibrium block. Since rice has a low rate of LD decay, this
 533 makes it more difficult to identify causal genes (Wang et al., 2020). Therefore, the local LD analysis was used
 534 to define LD clumps surrounding the index SNPs, using LD clumping in PLINK, where the local LD between
 535 SNPs is considered. A strong LD between SNPs is one of the three criteria that must be simultaneously
 536 satisfied. The other two criteria are p-value threshold set to 0.01 and physical distance set to 250 kb, given
 537 with the R^2 value. We considered SNPs with $-\log^{10}(\text{p-value}) > 5$ as index SNPs to perform the analysis and
 538 clump SNPs with p-value > 4. For the determination of loci of interest for weed-competitiveness, we focused

on the core traits culm height, shoot area, solidity and number of leaves. For culm height and number of leaves single significant SNPs were not found to be surrounded by other significant SNPs within LD and therefore did not meet our selection criteria. Since, dry weight is highly correlated with the traits of branchiness, we included the peaks found for dry weight as a representative locus for branchiness and similarly the loci for plant height as a representative of height related traits.

Gene models: Genetic regions covered by significant SNPs were searched for candidate genes using two different gene annotation models, which were then merged: the Michigan State University (MSU; 31 Oct. 2011 - Release 7; <http://rice.plantbiology.msu.edu/>) and the Rice Annotation Project Database (RAP-DB; 24 March 2020; <https://rapdb.dna.affrc.go.jp/>). Other data resources used, were the gene ID converter (<https://rapdb.dna.affrc.go.jp/tools/converter>), GALAXY – rice genome browser (http://13.250.174.27:8080/?tool_id=getgenes&version=1.0.0&__identifier=pxuu9t4bnk) and SNP seek (<http://snp-seek.irri.org/>).

Haplotype analysis

In order to facilitate the identification of candidate genes within the found loci related to the canopy architecture, we performed haplotype analysis spanning the coding sequence regions of the genes within each locus. For each locus, we used the combined gene model annotation (MSU and RAP-DB) to identify the coding sequences belonging to individual genes (Supplemental Table 7). We subsequently compiled all SNPs that were within the coding sequence region into one haplotype and grouped all studied varieties based on their haplotype sequence. The haplotypes represented by 2 or less varieties were excluded from the analysis, due to low representation. Based on the haplotype grouping for each coding sequence, we performed a t-test for significant differences between the most abundant haplotype with all the other identified haplotypes for all measured traits. The individual haplotypes are represented by A/T, where A stands for reference accession sequence, and T for any alternative variant. Supplemental Data 8 contains the full list of coding sequences of genes within the defined loci of interest.

563

564 **Acknowledgements**

565 We thank Ricardo Eugenio and James Edgane for their substantial assistance in the phenotyping at the
 566 International Rice Research Institute and Yorrit van de Kaa and Alba Schielen for their help with the
 567 experiments at Utrecht University. We thank Roel van Bezouw and Tom Theeuwen for helpful discussions
 568 about GWAS and Rens Voesenek, Evelyn Aparicio (Nelen & Schuurmans), Jochem Evers (WUR) and Jonne
 569 Rodenburg (University of Greenwich) for useful discussions on this research project.

595 **Supplemental Data 3** (<https://doi.org/10.5281/zenodo.4730232>): Association results for GWAS with
596 lme4QTL using a mixed linear model (MLM) based on the lme4QTL protocol, for shoot area, hull area,
597 perimeter, plant height, culm height, leaf length, solidity, number of leaves, number of tillers, dry weight,
598 droopiness, leaf angle, tiller angle and the Sum of normalized traits.

599 **Supplemental Data 4:** Genetic regions underlying shoot architectural traits and seedling vigour in 4-week-
600 old rice seedlings. Single-trait genome-wide association studies (GWAS) using a mixed linear model (MLM)
601 based on the lme4QTL protocol, for droopiness, leaf angle, tiller angle, SUM_norm_traits, number of leaves,

602 number of tillers, culm height, leaf length hull area and perimeter. The Manhattan plots depict the single
603 nucleotide polymorphisms (SNPs) with minor allele frequencies (MAF) > 0.05. Negative logarithmic P-values
604 on the y-axis, for 1.7 M SNPs across the 12 rice chromosomes along the x-axis. P-values of association results
605 for all traits can be found in Supplemental Data 3.

606 **Supplemental Data 5:** Genetic regions underlying shoot architectural traits and seedling vigour in 4-week-
607 old rice seedlings. Single-trait GWAS using a mixed linear model (MLM) with the GAPIT package in R, for
608 shoot area, hull area, perimeter, plant height, culm height, leaf length, solidity, number of leaves, number of
609 tillers, dry weight, droopiness, leaf angle, tiller angle and the Sum of normalized traits. The Manhattan plots
610 depict the single nucleotide polymorphisms (SNPs) with minor allele frequencies (MAF) > 0.05. Negative
611 logarithmic P values on the y-axis, for 1.7 M SNPs across the 12 rice chromosomes along the x-axis.

612 **Supplemental Data 6:** QQ plots with negative logarithmic P values for observed on the y-axis and expected
613 SNP - trait associations on the x-axis.

614 **Supplemental Data 7:** Haplotype groups for all determined loci of interest with their phenotype effect for 13
615 investigated shoot traits.

616 **Supplemental Data 8:** List of sequences of genes for loci of interest, with haplotypes for screened varieties.

617 **Tables**

618

619 **Table 1:** Description of 13 investigated shoot traits.

Trait	Unit	Description
Number of leaves		Number of all visible green leaf blades
Number of tillers		Number of side branches classified as tillers as soon as it splits off the culm having two leaves
Total plant height	cm	Height from soil to the straightened topmost leaf tip
Culm height	cm	Mother stem - from soil to highest node, where youngest leaf blade bends off
Leaf length	cm	Length of longest leaf blade
Projected shoot area	cm ²	All green leaf area projected from top view
Convex hull area	cm ²	Smallest area enclosing outermost leaf tips
Shoot perimeter	cm	Outline of the projected shoot area
Leaf angle	°	Angle between culm and leaf blade initiation measured for second and third leaf
Tiller angle	°	Angle between the culm and tillers, measured for the left and right outermost tillers
Leaf droopiness	°	Interception angle of two tangents aligned to initiation and tip of leaf blade measured for second and third leaf
Dry weight shoot	g	Dry matter of shoot biomass after drying in oven at 70 C for 48 h
Solidity		Ratio of projected shoot area divided by convex hull area

620

621 **Table 2: Core groups of shoot traits.** For core groups with multiple traits, we have selected a representative
622 trait as the core trait, shown in bold.

Core groups	Measured shoot architectural traits
Area	Projected shoot area , convex hull area, perimeter
Branchiness	Number of leaves , number of tillers, dry weight
Height	Culm height , leaf length, plant height
Solidity	Solidity
Leaf angle	Leaf angle
Tiller angle	Tiller angle
Droopiness	Droopiness

623

624

Table 3: Shading Rank for ten highest and ten lowest ranking varieties, and for varieties of special interest (Mudgo, IR 64-21, Nipponbare and Della) with normalized core trait values (between 0 as lowest and 100 highest) compared to the min and max values within the screened panel and the sum of the core traits. Varieties in bold are visualized in Figure 3. The Shading Rank ranges from 344 as the highest and 1 as the lowest. The list of Shading Ranks for the entire panel can be found in Supplemental Table 3.

Variety	Subpopulation	Shoot area.norm	Number of leaves.norm	Solidity.norm	Culm height.norm	Leaf angle.norm	Tiller angle.norm	Droopiness.norm	SUM_norm_traits	Shading Rank

632 **Table 4: Loci of interest for traits of core groups for shading potential** (solidity, plant height, shoot area,
633 and dry weight) with significant SNPs (LOD > 5 as index SNPs) and clumped SNPs (LOD > 4) in local LD
634 up- and downstream. Full list of SNP positions in loci of interest can be found in Supplemental Table 7.

Trait	Locus	Chromosome	Index SNP_ID	Position	Span_locus [kb]	Coordinates_locus [kb]
Solidity	Locus1	3	SNP-3.35500735.	35507867	404	chr3:35347550..35752533
Plant height	Locus2	5	SNP-5.20612311.	20674871	59	chr5:20621852..20680955
Plant height	Locus3	6	SNP-6.13994152.	13995152	240	chr6:13754207..13995152
Shoot area	Locus4	7	SNP-7.25787749.	25788744	146	chr7:25659129..25806056
Dry weight	Locus5	7	SNP-7.25766799.	25767794	35	chr7:25767794..25803081
Dry weight	Locus6	11	SNP-11.6059294.	6063543	23	chr11:6039907..6063875

635

Table 5: Summary of determined loci of interest with the Locus ID and gene annotation. Loci represented in Figure 6 are highlighted in bold. Full list of SNP positions in loci of interest with gene annotation and gene ontology categories can be found in Supplemental Table 7.

Trait	Locus	Chromosome	Locus_ID	Gene annotation
Solidity	Locus1	3	Os03g0841800	GSK3/SHAGGY-like kinase
			Os03g0841850	Hypothetical protein.
			Os03g0843700	FAR1 domain containing protein.
			Os03g0845000	Similar to Pirin-like protein.
			Os03g0845700	Similar to RPB17 (Fragment).
			Os03g0845800	Conserved hypothetical protein.
			Os03g0848700	Coiled-coil, nucleotide-binding, and leucine-rich repeat protein
Plant height	Locus2	5	Os05g0420500	Conserved hypothetical protein.
			Os05g0420600	Cytochrome c.
			Os05g0420900	Conserved hypothetical protein.
Plant height	Locus3	6	Os06g0269300	TolB-like domain containing protein.
			Os06g0346300	acyl-CoA oxidase/ oxidoreductase
Shoot area	Locus4	7	Os07g0623200	Heavy metal transporter protein; ATPase, P-type.
			Os07g0623501	Hypothetical gene.
			Os07g0623600	Similar to mRNA, clone: RTFL01-43-H20.
Dry weight	Locus5	7	Os07g0623200	Heavy metal transporter protein; ATPase, P-type.
			Os07g0623501	Hypothetical gene.
			Os07g0623600	Similar to mRNA, clone: RTFL01-43-H20.
Dry weight	Locus6	11	Os11g0216000	Pyruvate kinase family protein.

639 Figure legends

640

641 **Figure 1: Shoot traits in rice differ between subpopulations.** Distribution of investigated shoot traits in the
642 screened diversity panel. The plots represent the trait value (y-axis) observed for varieties grouped according
643 to different subpopulations on x-axis. A) Shoot area [cm²], B) Hull area [cm²], C) Perimeter [cm], D) Solidity,
644 E) Dry weight [g], F) number of leaves, G) Number of tillers, H) Plant height [cm], I) Leaf length [cm], J)
645 Culm height [cm], K) Leaf angle [°], L) Tiller angle [°] and M) Droopiness [°]. Each data point represents the
646 mean out of 8 replicates for each of the 344 varieties. The colours represent different groups of subpopulations,
647 ind – *indica*, aus, adm – *admixed*, aro – *aromatic*, trj – *tropical japonica* and tej – *temperate japonica*. The
648 letters in the graphs represent the significantly different groups, as determined with Tukey's HSD with p-value
649 < 0.05. Mean values for all 13 traits and the sum of the normalized traits including results for Tukey's pairwise
650 post hoc test can be found in Supplemental Table 2.

651 **Figure 2: Correlation and clustering of 13 shoot traits defines core groups of traits.** A) Pearson Correlation
652 coefficients between traits. The colour and size of the circles reflect the strength of the correlation. B)
653 Hierarchical Cluster Analysis. Traits are clustered using ward.D2 method. Rows represent 13 studied shoot
654 traits. The values of individual samples are normalized per trait using z-Fisher transformation scaled prior to
655 clustering. Based on a cut off at seven clusters and together with the correlation coefficients, we grouped
656 together the traits into defined core groups.

657 **Figure 3: Visualization of shading potential in the investigated rice diversity panel based on cor traits**
658 **for the Shading Rank.** A) - D) Scatter plots showing the distribution of 344 rice varieties in pair-wise
659 combination of four core traits, shoot area, number of leaves, solidity and culm height. Representative high
660 (344, 343 and 330) and low (49 and 1) ranking varieties together with Nipponbare (73) and IR 64-21 (74) are
661 highlighted in colours. B) Top view images of representative varieties, with colour coded frames. Numbers are
662 respective Shading Ranks as found in Table 3.

663 **Figure 4: Shading Rank predicts the canopy shading capacity of high and low ranking rice varieties.**
664 Significant difference in shading capacity between canopies of different rice varieties at five weeks after
665 sowing. The plot shows the reduction in light intensity (% PAR) measured at the ground level under the rice
666 canopy compared to above the canopy, for different rice varieties on x-axis, where Della and Luk Takhar were
667 classified as non-competitive (blue) with Shading ranks of 49 and 1, respectively and Mudgo and Shim Balte
668 as competitive (green) with Shading Ranks of 330 and 344, respectively. Letters indicate significance (ANOVA
669 with Tukey's pairwise comparison post hoc test p < 0.05). Measured PAR values (photosynthetic active
670 radiation of 400-700 nm waveband) can be found in Supplemental Table 4.

671 **Figure 5: GWAS identifies putative the genetic regions underlying shoot architectural traits** and seedling
672 vigour in 4-week-old rice seedlings, reflecting the early vegetative growth stage. We used single-trait genome-
673 wide association studies (GWAS) with a mixed linear model (MLM) for plant height, solidity, shoot area and

674 dry weight. The Manhattan plots depict the single nucleotide polymorphisms (SNPs) with minor allele
675 frequencies (MAF) > 0.05. Negative logarithmic p-values on the y-axis, for 1.7 M SNPs across the 12 rice
676 chromosomes along the x-axis. Dashed red lines indicate significance threshold set at $-\log_{10}(p\text{-value}) > 7.5$.
677 Genomic regions highlighted in green are loci of interest (numbered L1 – L6).

678 **Figure 6: Haplotypes for genes of interest associated with increased trait values.** Locus 1 was detected for
679 solidity with haplotypes in the coding sequence of the genes A) Os03g0845000 consisting of two SNPs and
680 B) Os03g0845700 consisting of one SNPs. Locus 2 was detected for plant height with haplotypes in the coding
681 sequence of the genes C) Os05g0420600 consisting of four SNPs and B) Os05g0420900 consisting of six
682 SNPs. Locus 4 was detected for shoot area and dry weight with haplotypes in the coding sequence of the gene
683 Os07g0623200 consisting of four SNPs shown for E) shoot area and F) dry weight. Locus 6 was detected for
684 dry weight encoding only one gene G) Os11g0216000 with haplotypes consisting of nine SNPs. Dot plots for
685 t-test, comparing each haplotype with the most abundant (blue) haplotype, on core traits for shading potential.
686 Y-axis trait value, x-axis groups of haplotypes. Additional information about the detected genes can be found
687 in Table 5 and dot plots for haplotypes for all 13 traits found in loci of interest are shown in Supplemental
688 Figure 5.

Figures

837

Figure 1: Shoot traits in rice differ between subpopulations. Distribution of investigated shoot traits in the screened diversity panel. The plots represent the trait value (y-axis) observed for varieties grouped according to different subpopulations on x-axis. A) Shoot area [cm²], B) Hull area [cm²], C) Perimeter [cm], D) Solidity, E) Dry weight [g], F) number of leaves, G) Number of tillers, H) Plant height [cm], I) Leaf length [cm], J) Culm height [cm], K) Leaf angle [°], L) Tiller angle [°] and M) Droopiness [°]. Each data point represents the mean out of 8 replicates for each of the 344 varieties. The colours represent different groups of subpopulations, ind – *indica*, aus, adm – *admixed*, aro – *aromatic*, trj – *tropical japonica* and tej – *temperate japonica*. The letters in the graphs represent the significantly different groups, as determined with Tukey's HSD with p-value < 0.05. Mean values for all 13 traits and the sum of the normalized traits including results for Tukey's pairwise post hoc test can be found in Supplemental Table 2.

846

847 **Figure 2: Correlation and clustering of 13 shoot traits defines core groups of traits.** A) Pearson Correlation coefficients between
848 traits. The colour and size of the circles reflect the strength of the correlation. B) Hierarchical Cluster Analysis. Traits are clustered using
849 ward.D2 method. Rows represent 13 studied shoot traits. The values of individual samples are normalized per trait using z-Fisher
850 transformation scaled prior to clustering. Based on a cut off at seven clusters and together with the correlation coefficients, we grouped
851 together the traits into defined core groups.

852

853 **Figure 3: Visualization of shading potential in the investigated rice diversity panel based on cor traits for the Shading Rank.** A) -
854 D) Scatter plots showing the distribution of 344 rice varieties in pair-wise combination of four core traits, shoot area, number of leaves,
855 solidity and culm height. Representative high (344, 343 and 330) and low (49 and 1) ranking varieties together with Nipponbare (73) and
856 IR 64-21 (74) are highlighted in colours. B) Top view images of representative varieties, with colour coded frames. Numbers are respective
857 Shading Ranks as found in Table 3.

Figure 4: Shading Rank predicts the canopy shading capacity of high and low ranking rice varieties. Significant difference in shading capacity between canopies of different rice varieties at five weeks after sowing. The plot shows the reduction in light intensity (% PAR) measured at the ground level under the rice canopy compared to above the canopy, for different rice varieties on x-axis, where Della and Luk Takhar were classified as non-competitive (blue) with Shading ranks of 49 and 1, respectively and Mudgo and Shim Balte as competitive (green) with Shading Ranks of 330 and 344, respectively. Letters indicate significance (ANOVA with Tukey's pairwise comparison post hoc test $p < 0.05$). Measured PAR values (photosynthetic active radiation of 400-700 nm waveband) can be found in Supplemental Table 4.

865

866 **Figure 5: GWAS identifies putative the genetic regions underlying shoot architectural traits** and seedling vigour in 4-week-old rice
867 seedlings, reflecting the early vegetative growth stage. We used single-trait genome-wide association studies (GWAS) with a mixed linear
868 model (MLM) for plant height, solidity, shoot area and dry weight. The Manhattan plots depict the single nucleotide polymorphisms (SNPs)
869 with minor allele frequencies (MAF) > 0.05. Negative logarithmic p-values on the y-axis, for 1.7 M SNPs across the 12 rice chromosomes
870 along the x-axis. Dashed red lines indicate significance threshold set at $-\log_{10}(p\text{-value}) > 7.5$. Genomic regions highlighted in green are
871 loci of interest (numbered L1 – L6).

872

873 **Figure 6: Haplotypes for genes of interest associated with increased trait values.** Locus 1 was detected for solidity with haplotypes
874 in the coding sequence of the genes A) Os03g0845000 consisting of two SNPs and B) Os03g0845700 consisting of one SNPs. Locus 2
875 was detected for plant height with haplotypes in the coding sequence of the genes C) Os05g0420600 consisting of four SNPs and B)
876 Os05g0420900 consisting of six SNPs. Locus 4 was detected for shoot area and dry weight with haplotypes in the coding sequence of
877 the gene Os07g0623200 consisting of four SNPs shown for E) shoot area and F) dry weight. Locus 6 was detected for dry weight encoding
878 only one gene G) Os11g0216000 with haplotypes consisting of nine SNPs. Dot plots for t-test, comparing each haplotype with the most
879 abundant (blue) haplotype, on core traits for shading potential. Y-axis trait value, x-axis groups of haplotypes. Additional information about
880 the detected genes can be found in Table 5 and dot plots for haplotypes for all 13 traits found in loci of interest are shown in Supplemental
881 Figure 5.
