26 **Abstract**

27 H₂S is a potent gasotransmitter in eukaryotes and bacteria. Host-derived H₂S has been
 28 shown to profoundly alter *M. tuberculosis* (*Mtb*) energy metabolism and growth. However,
 29 compelling evidence for endogenous production of H₂S and its role in *Mtb* physiology is
 30 lacking. We show that multidrug-resistant and drug-susceptible clinical *Mtb* strains produce
 31 H₂S, whereas H₂S production in non-pathogenic *M. smegmatis* is barely detectable. We
 32 identified Rv3684 (Cds1) as an H₂S-producing enzyme in *Mtb* and show that *cds1* disruption
 33 reduces, but does not eliminate, H₂S production, suggesting the involvement of multiple
 34 genes in H₂S production. We identified endogenous H₂S to be an effector molecule that
 35 maintains bioenergetic homeostasis by stimulating respiration primarily via cytochrome *bd*.
 36 Importantly, H₂S plays a key role in central metabolism by modulating the balance between
 37 oxidative phosphorylation and glycolysis, and functions as a sink to recycle sulfur atoms
 38 back to cysteine to maintain sulfur homeostasis. Lastly, *Mtb*-generated H₂S regulates redox
 39 homeostasis and susceptibility to anti-TB drugs clofazimine and rifampicin. These findings
 40 reveal previously unknown facets of *Mtb* physiology and have implications for routine
 41 laboratory culturing, understanding drug susceptibility, and improved diagnostics.

42

43

44 Introduction

45 Tuberculosis (TB) remains a major cause of morbidity and mortality in underdeveloped and
46 developing countries. While substantial progress has been made in understanding the
47 biological basis of *Mtb* pathogenesis, precisely how *Mtb* physiology and metabolism
48 contribute to persistence, pathogenesis and drug resistance is poorly understood.

49 The gasotransmitters carbon monoxide (CO) and nitric oxide (NO) have important
50 roles in *Mtb* physiology¹⁻⁴. A third gasotransmitter, hydrogen sulfide (H₂S), is involved in a
51 wide variety of physiological processes in eukaryotes and prokaryotes⁵. H₂S is a weak acid
52 in solution and at physiological pH exists predominantly as a hydrosulfide anion (HS⁻, 75-
53 80%), with the rest as H₂S (20-25%) and only trace amounts of S²⁻⁶. Notably, H₂S diffuses
54 easily through cell membranes unlike its deprotonated conjugate bases HS⁻ and S²⁻. The
55 complex nature of H₂S in solution, and its volatility, make this molecule very difficult to
56 measure and challenging to work with^{6,7}. Furthermore, H₂S can be generated non-
57 enzymatically from media components⁸, and therefore methods for measuring H₂S require
58 rigorous validation.

59 Cysteine (Cys) is frequently used as a substrate by bacterial Cys desulfhydrases for
60 H₂S production. Intracellular Cys levels require careful control since excessive levels can
61 stimulate oxidative stress via the Fenton reaction, which produces hydroxyl radicals⁹. On
62 the other hand, H₂S is also a substrate for Cys biosynthesis, which is required for the
63 formation of low molecular weight thiols such as mycothiol (MSH) and ergothioneine (EGT)
64 and biogenesis of iron sulfur cluster proteins^{10,11}. The ability of bacteria to produce H₂S has
65 been widely used as a diagnostic test and for taxonomic purposes^{12,13}.

66 H₂S production in bacteria has been attributed mainly to the enzymatic activity of
67 cystathionine β-synthase (CBS), cystathionine γ-lyase (CSE) and 3-mercaptopyruvate
68 sulfurtransferase (3MST)^{14,15}. Addition of Cys to bacterial cultures has been shown to
69 stimulate H₂S production¹⁴⁻¹⁷. In both bacterial and mammalian cells, Cys is used as a
70 substrate by CBS and CSE to produce H₂S^{15,18,19}. Although bacterial production of H₂S was
71 initially considered to be a by-product of sulfur metabolism with unclear physiological
72 relevance, studies in several bacterial species have shown that disrupting H₂S-producing
73 genes increases antibiotic susceptibility¹⁵. Obviously, these findings have important
74 implications for understanding drug resistance in bacterial pathogens. In *E. coli*, 3MST
75 produces the majority of cellular H₂S from Cys¹⁴ and genetic disruption of this gene leads to
76 increased sensitivity to oxidative stress¹⁴, implicating 3MST-derived H₂S in maintaining redox
77 homeostasis.

78 Several studies have shown that H₂S reversibly inhibits cytochrome c oxidase
79 (Complex IV) at high concentrations and stimulates mitochondrial respiration at low
80 concentrations^{20,21}. We have recently shown that exogenous H₂S also targets the *Mtb*

electron transport chain to increase respiration and ATP levels leading to increased growth²², and that host-generated H₂S exacerbates TB in mice^{22,23}. Further, CSE and 3MST protein levels are substantially increased in human tuberculous lung tissue, and it has been proposed that *Mtb* triggers supraphysiological levels of host-generated H₂S at the site of infection to suppress host immunity, thereby exacerbating disease²³. Notably, *Mtb* senses host-generated H₂S during infection and reprograms its metabolism accordingly²².

H₂S plays important roles in modulating mammalian immunity, although its effects have been shown to be both pro- and anti-inflammatory^{18,24}. Thus, H₂S produced by bacterial pathogens could act as a signaling molecule in the host, potentially exacerbating disease. The presence of *Mtb* homologues of H₂S-producing enzymes identified in KEGG (<https://www.genome.jp/kegg/>) and several biochemical studies²⁵⁻²⁹ suggest that *Mtb* has the capacity to produce H₂S. However, formal genetic and biochemical demonstration of H₂S production by *Mtb* cells and its functions in *Mtb* physiology is lacking. Due to the diverse roles H₂S plays in prokaryotic biology and bacterial classification, clear evidence that *Mtb* produces H₂S is expected to widely influence our understanding of *Mtb* physiology, disease, and diagnostics.

Here we test the hypothesis that *Mtb* produces H₂S by measuring H₂S production in drug-susceptible (DS) and multidrug-resistant (MDR) clinical strains, laboratory *Mtb* strains, and non-pathogenic mycobacterial species. We then identified a gene and corresponding protein responsible for H₂S production in *Mtb*. We generated a *Mtb* knockout strain and utilized flow cytometry, extracellular metabolic flux analysis, ¹³C stable isotope analyses and drug studies to determine the effect of endogenously produced H₂S on respiration, central metabolism, redox balance, and drug susceptibility. We expect our findings to broadly impact our understanding of *Mtb* physiology and drug resistance.

Results

H₂S production by mycobacteria

Since H₂S can be spontaneously generated by media components⁸, and some H₂S detection methods are prone to artifacts [e.g., non-specific reaction of lead acetate strips with sulfides¹²], we carefully controlled the experimental conditions under which H₂S levels were measured in solution or in a headspace using validated techniques. Three different methods were employed to measure H₂S production in mycobacteria; the widely-used lead acetate [Pb(Ac)₂] method, the bismuth chloride [BiCl₃; (BC)] method^{30,31} and a highly sensitive amperometric microsensor (Unisense A/S, Denmark)³².

We first used lead acetate strips to detect the presence of H₂S in the headspace of mycobacterial cultures (Fig. 1a). This method is based on the reaction of lead acetate with

H₂S to form lead sulfide (PbS), seen as a dark colored precipitate on the strip³³. We assessed the production of H₂S in slow-growing laboratory strains [*Mtb* H37Rv and *Mtb* CDC1551 (CDC)], clinical strains [drug-sensitive (DS) and multidrug-resistant (MDR)], *M. bovis* BCG (BCG), *M. bovis* (*Mbo*), as well as the fast-growing mycobacterial strain *M. smegmatis* (*Msm*), inoculated to the same optical density. Notably, all mycobacteria tested produce H₂S (Fig. 1a). Since H₂S production appears to be growth and strain dependent, we quantified lead sulfide formation on lead acetate strips and normalized the values to culture density as described previously³⁴ (Fig. 1b). BCG, *Mbov*, and the DS *Mtb* clinical strain produce significantly less H₂S than laboratory strains *Mtb* H37Rv and CDC. Notably, slow-growing pathogenic *Mtb* strains, particularly the MDR strains, produce the highest levels of H₂S, whereas H₂S production in *Msm* was virtually undetectable (Fig. 1b).

To verify the results shown in Fig. 1a and b, we employed a BC microplate assay to detect H₂S in mycobacterial culture media and cell lysates. The BC microplate assay relies on the reaction of BiCl₃ with H₂S to generate bismuth sulfide (Bi₂S₃), a brownish black precipitate³¹. Importantly, BC-based H₂S measurements are not influenced by cell proliferation, since the high concentrations of EDTA and Cys required for the assay inhibit growth. Furthermore, EDTA prevents the spontaneous generation of H₂S from Cys and iron⁸. In the BC assay, we observed that only live *Mtb* produce H₂S, and not heat-killed bacilli or media alone (Fig. 1c), and that H₂S levels positively correlated with the concentrations of Cys present in the growth medium (Fig. 1d, Supplementary Fig. 1). Several H₂S-producing enzymes use Cys as substrate and pyridoxal 5-phosphate (PLP) as a co-factor^{18,19}. As shown in Fig. 1e, addition of PLP significantly increased H₂S production in *Mtb* lysates containing various concentrations of Cys. This suggests that the BC-based method is effective for measuring H₂S in culture medium and cell lysates, and that at least one PLP-dependent enzyme is responsible for H₂S production in *Mtb*.

Next, we attempted to characterize the H₂S-producing enzymes in *Mtb* by using specific enzyme inhibitors. Aminooxyacetic acid (AOAA) is an inhibitor of PLP-dependent enzymes, including cystathionine β-synthase (CBS) and cystathionine γ-lyase, whereas DL-propargylglycine (PAG) inhibits only cystathionine γ-lyase (CSE)³⁵. Addition of AOAA resulted in a concentration-dependent reduction of H₂S in intact cells (Fig. 1f) and in lysates (Fig. 1g). In contrast, H₂S levels were not significantly altered by PAG in either intact cells (Fig. 1h) or lysates (Fig. 1i). Again, these findings suggest that at least one PLP-dependent enzyme is a major contributor to H₂S production in *Mtb*.

To further support these findings, we used a highly sensitive amperometric H₂S microsensor (Unisense, A/S, Denmark) to directly detect H₂S. Using this method, we observed that, compared to untreated controls, the addition of 1 mM Cys resulted in a 3-fold increase in H₂S levels in the media of dispersed *Mtb* cultures, or in the corresponding

cleared media containing pelleted cells after 72 hours of incubation (Fig. 1j). In addition, this microsensor allowed us to monitor H₂S production in *Mtb* lysates using a single Cys concentration (Fig. 1k) or increasing Cys concentrations in real time (Fig. 1l), supporting our findings shown in Fig. 1e. In contrast, when AOAA was pre-incubated with the lysate, no H₂S was produced following addition of Cys (Fig. 1m), indicating complete inhibition of H₂S-producing activity.

In summary, using three different methods we provide evidence that laboratory and clinical strains of *Mtb* produce H₂S. We show that this activity is PLP-dependent, is inhibited by AOAA and not PAG, and uses Cys as a sulfur source. An intriguing finding was the significant variation in H₂S production among MDR and laboratory strains of *Mtb*, which is growth- and species-dependent. These findings have important implications for routine culturing of *Mtb* and improved diagnostics.

Identification of H₂S-producing enzymes in *Mtb*

We searched the Kyoto encyclopedia of genes and genomes (KEGG) database (<https://www.genome.jp/kegg/>) for enzymes encoded by *Mtb* H37Rv involved in H₂S production. We identified 11 enzymes putatively involved in the metabolism of sulfur, sulfur-containing amino acids and H₂S (Supplementary Table 1). CBS is a well-studied enzyme that produces H₂S in mammalian and bacterial cells, and *Mtb* encodes an ortholog of CBS, Rv1077 (<https://www.genome.jp/kegg/>) (Supplementary Table 1). To determine the role of Rv1077 in H₂S production, we deleted *rv1077/cbs* in *Mtb* H37Rv (Δcbs) using specialized phage transduction³⁶. Analysis of H₂S production in intact Δcbs cells or lysates revealed that H₂S production in Δcbs is not reduced compared to wild-type (WT) *Mtb* (Supplementary Fig. 2a-c).

We then pursued a biochemical approach to identify H₂S-producing enzymes in *Mtb*. In this approach, equal amounts of mycobacterial lysates were resolved on non-denaturing polyacrylamide gels and enzymatic production of H₂S was detected by applying the BC assay solution directly to the gel³⁷. Fig. 2a shows the formation of Bi₂S₃ resulting from H₂S production in various mycobacteria, seen as dark coloured bands of different intensities in the gel. Notably, addition of AOAA prior to the BC assay solution delayed the emergence and reduced the intensity of the major H₂S-producing band (Fig. 2b), consistent with the reduction in H₂S production observed with AOAA in microplate assays (Fig. 1f and 1g). Further, H₂S production was markedly increased in the presence of PLP, suggesting that the prominent dark band contained the same enzyme assayed in Fig. 1e, where PLP also increased the H₂S-producing activity. Moreover, in the absence of PLP, the H₂S-producing activity was completely abolished with AOAA (Fig. 2b).

We next performed in-gel tryptic digestion of the main H₂S-producing band from *Mtb* (Fig. 2c) followed by LC-MS/MS analysis. Several overlapping peptide fragments were identified with high confidence which identified Rv3684 as the putative H₂S-producing enzyme (Fig. 2c). Notably, Rv3684 is annotated as belonging to the Cys synthase/cystathionine β -synthase protein family (Mycobrowser.epfl.ch) (Supplementary Fig. 3). Importantly, we noticed an annotation ambiguity regarding the exact open reading frame (ORF) of *rv3684*. Based on our LC MS/MS data, we found that the actual start codon of the *rv3684* ORF overlaps the stop codon of *rv3683*, and that these ORFs are in different coding frames (Supplementary Fig. 4). On this basis, we conclude that the *rv3684* ORF has been incorrectly annotated in Mycobrowser.epfl.ch, resulting in omission of the first 66 nucleotides.

CBS and CSE can use Cys as a substrate to generate H₂S and other products such as serine (CBS) or pyruvate (CSE) (Fig. 2d). To characterize the Rv3684 enzymatic activity, Rv3684 was overexpressed in *E. coli* and purified (Fig. 2e). Using Cys as a substrate, we determined that Rv3684 produces H₂S and pyruvate, as shown by the in-gel BC assay (Supplementary Fig. 5a) and LC-MS/MS analysis (Fig. 2f), indicating this enzyme is functionally distinct from CBS. We next determined the initial velocities of H₂S production at increasing Cys concentrations via the BC assay. From these data we determined the K_m of Rv3684 to be 11.26 $\pm$ 0.75 mM with a k_{cat} of 78.71 $\pm$ 12.72 S⁻¹ (Fig. 2g). These data strongly suggest that Rv3684 catalyzes the conversion of Cys to form H₂S, pyruvate and ammonia in an α , β -elimination reaction analogous to CSE (Fig. 2h)¹⁹. Hence, we designate Rv3684 as a cysteine desulphydrase enzyme (Cds1).

In sum, we have employed a non-denaturing in-gel BC assay that demonstrates the activity of H₂S-producing enzymes in mycobacterial lysates and identified Cds1 as a H₂S-producing enzyme in *Mtb*. Identification of the enzymatic products indicates that Cds1 is a cysteine desulphydrase that generates H₂S and pyruvate from Cys.

Genetic disruption of *rv3684* reduces H₂S production and slows *Mtb* growth in the presence of Cys

To characterize the *rv3684* (*cds1*) genetic locus, we used *Mtb* CDC1551 transposon mutants *Tn::rv3682* (*ponA2*) and *Tn::rv3683*, positioned upstream of *cds1* (Fig. 3a). Notably, we observed that these mutants exhibited consecutively reduced H₂S production from equal amounts of cell lysate (Fig. 3b), confirming that *cds1* encodes an H₂S-producing enzyme and that this locus is subject to a strong polar effect. Next, we created a *cds1* deletion mutant in *Mtb* H37Rv (Δ *cds1*) using specialized phage transduction³⁶ (Supplementary Fig. 5b). We observed no Bi₂S₃ staining indicative of H₂S production in Δ *cds1* lysates in the in-gel BC assay (Fig. 3c), and significantly reduced H₂S production in intact Δ *cds1* cells (Fig.

3d) and lysates (Fig. 3e). Genetic complementation of *cds1* in $\Delta cds1$ cells, *Mtb* $\Delta cds1::hsp_{60}-cds1$ (*comp*) restored H₂S production (Fig. 3c-e). As shown in Fig. 3d, the amount of H₂S production in WT *Mtb* and *comp* cells are virtually identical. However, H₂S production in *comp* lysates exceeded that of WT *Mtb* (Fig. 3c and 3e), suggesting that Cys availability is limiting in intact *comp* cells, and that Cys import likely influence H₂S production in *Mtb*. Of note, H₂S production was reduced, but not eliminated in $\Delta cds1$ cells (Fig. 3d), suggesting the presence of additional H₂S-producing enzymes in *Mtb*. This is consistent with the appearance of a second band in our in-gel BC assay (Fig. 2a). In contrast, we observed no H₂S production in $\Delta cds1$ lysates (Fig. 3e). This is not unexpected, since H₂S-producing enzymes may require specific substrates, cofactors (e.g., NADPH, NADH, heme) and may be influenced by environmental conditions (e.g., oxygen)³⁸.

Since exogenous and host-derived H₂S supports *Mtb* bioenergetics and growth²², we determined the consequence of *cds1* deletion on *Mtb* growth in medium containing Cys, a major source of sulfur and a substrate of Cds1 for H₂S production. Compared to WT and *comp* cells, $\Delta cds1$ cells exhibited a significant growth defect in the presence of 4 mM Cys (Fig. 3f). This finding is analogous to studies in *E. coli* where disruption of D-cysteine desulfhydrase activity renders the bacteria susceptible to D-cysteine³⁹. This suggests that Cds1 can mitigate toxic levels of Cys by converting excess Cys into H₂S.

We investigated the role of *cds1* in *Mtb* survival during macrophage infection (Supplementary Fig. 6) and observed no significant difference in bacterial burden between WT *Mtb* and $\Delta cds1$ cells. This is not unexpected as *Mtb* encodes multiple enzymes that may produce H₂S (Supplementary Table 1) and conclusive demonstration of a role for H₂S in pathogenesis may require genetic disruption of multiple H₂S-producing genes and assessment in an *in vivo* model for TB. Since *Mtb* relies on lipid catabolism *in vivo*⁴⁰, we also investigated whether growth of $\Delta cds1$ cells is influenced by utilization of fatty acids as a sole carbon source. Medium containing glycerol as the carbon source showed optimal growth for all *Mtb* strains and no significant growth differences were observed between WT *Mtb* and $\Delta cds1$ cells in the presence of other fatty acids as the sole carbon source (Supplementary Fig. 7). In contrast, H₂S production by $\Delta cds1$ cells was significantly reduced compared to WT or *comp* cells in all media containing fatty acids as sole carbon sources (Supplementary Fig. 8). Notably, H₂S production by $\Delta cds1$ cells was prolonged in media containing acetate, propionate or butyrate compared to glycerol and cholesterol-containing media.

Bioinformatic analyses showed that a homolog of Cds1 with >76% identity is present in all mycobacterial species (Fig. 3g). Phylogenetic analysis revealed that orthologs are also present in bacteria other than *Mycobacterium* spp. (Fig. 3g) (e.g., *Pseudosporangium*, *Streptomyces* and *Rhodococcus* spp.). Further phylogenetic analyses of other sulfur

metabolizing enzymes in mycobacteria demonstrate that sulfur metabolizing enzymes like CysK2, CysM and CBS show substantial similarities to Cds1 (Fig. 3h). Of note was the similarity between Cds1 that converts Cys to H₂S, and CysK1, which utilizes H₂S as substrate to form Cys⁴¹.

In summary, using a series of biochemical and genetic approaches, we demonstrate that *Mtb* produces H₂S primarily through Cds1. We functionally complemented Δ *cds1* cells and show that genes upstream of *cds1* exert a strong polar effect on Cds1 levels, suggesting that *cds1* is in an operon with *rv3682* (*ponA2*) and *rv3683*. Lastly, we show that Cds1 is conserved in virtually all mycobacterial species with orthologs present in numerous other bacteria.

Conferring increased H₂S-generating activity to *M. smegmatis*

Msm has been widely used as a fast-growing surrogate for *Mtb* in numerous genetic and secretion studies⁴². Further, we observed that *Msm* produces very little H₂S in our in-gel BC assay (Fig. 1b). We reasoned that heterologous expression of *cds1* in *Msm* would allow the rapid study of how endogenous H₂S affects mycobacterial physiology. To this end, we transformed *Msm* with plasmids that express *cds1* under control of the *hsp*₆₀ promoter (*Msm-hsp*₆₀-*cds1*), or the *Mtb* wild-type ('native'; *wt*_p) promoter (*Msm-wt*_p-*cds1*). *Msm-hsp*₆₀-*cds1* and *Msm-wt*_p-*cds1* lysates generated Bi₂S₃ bands with a migration pattern similar to that in *Mtb* lysates. However, Bi₂S₃ formation was substantially increased compared to WT *Mtb*, likely due to *cds1* overexpression from multi-copy expression plasmids (Fig. 4a). We also observed a Bi₂S₃ band in WT *Msm* lysates, indicating the presence of an endogenously expressed H₂S-producing enzyme with migration properties distinct from *Mtb* Cds1. This *Msm* H₂S-producing band was not observed in *Msm-hsp*₆₀-*cds1* or *Msm-wt*_p-*cds1* lysates, possibly due to altered transcriptional or posttranscriptional regulation in the presence of overexpressed Cds1. H₂S production in *Msm-wt*_p-*cds1* and the *Msm-hsp*₆₀-*cds1* lysates (Fig. 4b) was more rapid and robust than in *Msm* containing the empty vector (*Msm*-pMV261) suggesting overproduction of Cds1, as observed in Fig. 4a. However, H₂S production in intact Cds1-producing *Msm* cells measured over time (Fig. 4c) or at an endpoint (Fig. 4D) was markedly lower than in the corresponding lysates (Fig. 4b), suggesting that the lower H₂S levels observed in *Msm* cells may be due to limitations in Cys transport.

We next examined the impact of overexpressed *cds1* on the growth of *Msm* cultured in media containing Cys (0, 8, 16 mM). *Msm-hsp*₆₀-*cds1* and *Msm-wt*_p-*cds1* maintained a significant growth advantage over control *Msm*-pMV261 after 48 hours in medium containing 8 mM Cys (Fig. 4e and f). These results suggest that Cds1 confers resistance to Cys-induced toxicity in *Msm* by converting excess Cys into H₂S. Hence, our data suggest that

due to its low capacity for H₂S production, *Msm* can be used as an effective surrogate for studying the effect of H₂S on mycobacterial physiology.

Endogenous H₂S stimulates respiration in *Mtb*

Several studies have shown that H₂S can inhibit or stimulate mammalian respiration in a concentration-dependent manner^{20,21}. Similarly, a recent study has shown that exogenous H₂S can stimulate *Mtb* cellular respiration²². On the other hand, biochemical studies have shown that H₂S inhibits purified *E. coli* cytochrome *bc₁/aa₃*^{22,43} and that cytochrome *bd* oxidase is resistant to inhibition by H₂S^{44,45}. Hence, we hypothesized that endogenous H₂S produced by Cds1 can modulate *Mtb* respiration. To test this hypothesis, we used extracellular metabolic flux analysis, a methodology developed for eukaryotic cells which we have optimized for real-time, quantitative study of *Mtb* respiration^{22,46}.

First, we measured the basal oxygen consumption rate (OCR) of $\Delta cds1$, which was ~40% lower than the basal rate in WT or *comp* (Fig. 5a). Of note, a reduction in respiration of this magnitude is highly significant in bioenergetic terms and suggests that endogenous H₂S stimulates *Mtb* respiration. Next, we sought to determine whether Cds1-generated H₂S acts as an effector to directly modulate basal respiration in *Mtb*. Several lines of evidence indicate that this is the case. Firstly, addition of Cys leads to increased respiration in *Mtb* in a concentration-dependent manner (Fig. 5b), whereas the OCR of $\Delta cds1$ cells is unchanged by the addition of 4 mM Cys, in contrast to WT and *comp* (Fig. 5c). Secondly, deletion of *cbs* (*rv1077*) in *Mtb* (Δcbs) did not significantly reduce the OCR compared to WT cells in the presence of 4mM Cys (Supplementary Fig. 9). Thirdly, addition of AOAA, an inhibitor of PLP-dependent enzymes such as Cds1, eliminated the Cys-stimulated increase in OCR in WT *Mtb* (Fig. 5d). Likewise, addition of AOAA followed by Cys decreased respiration in *Mtb* cells (Supplementary Fig. 10A), which was attributed to the inhibition of Cds1 and other PLP-dependant enzymes by AOAA. Importantly, AOAA alone has no significant effect on respiration in the absence of Cys (Supplementary Fig. 10B). Taken together, these data suggest that Cds1-generated H₂S is important for maintaining basal respiration in *Mtb*.

To further confirm that H₂S is the endogenous effector molecule modulating *Mtb* respiration, we exposed $\Delta cds1$ cells to exogenous H₂S and observed reversal of the respiratory defect in these cells (Supplementary Fig. 11). Next, we used an H₂S-degrading enzyme, O-acetylserine sulfhydrylase⁴¹ (OASS), in our bioenergetic assays (Supplementary Fig. 12). Using H₂S and O-acetylserine (OAS) as substrates, OASS catalyses a β -replacement reaction to produce Cys and acetate. Enzymatic activity of OASS was confirmed by monitoring a reduction in H₂S concentration using the Unisense microsensor (Fig. 5e). Sequential addition of NaHS increased H₂S levels whereas injection of purified OASS caused a rapid decrease in H₂S levels after addition of the substrate, OAS (Fig. 5e).

On this basis, we posited that addition of OASS and its substrate OAS would deplete H₂S produced by *Mtb*, resulting in a sustained or reduced OCR. Indeed, as shown in Fig. 5f, our data suggest that addition of OAS and purified OASS to wells containing *Mtb* prevents the Cys-mediated increase in OCR via degradation of *Mtb*-generated H₂S by OASS activity. Although a product of the OASS reaction is Cys, which can re-enter the cell as a substrate for H₂S production, Cys transport across the membrane is rate limiting. Hence, exogenous OASS depletes H₂S faster than Cys can be transported into the cytoplasm and used for H₂S production. Overall, OASS and OAS significantly reduces H₂S in our experimental system. Lastly, cytoplasmic H₂S may also be consumed by *Mtb* CysK1 using exogenous OAS as a substrate⁴¹. Indeed, addition of OAS and Cys to *Mtb* cells significantly reduced OCR compared to *Mtb* cells treated with Cys alone, suggesting CysK1 can consume excess H₂S depending on intracellular levels of OAS (Fig. 5g), and led to the model in Fig. 5h.

We next examined the mechanism whereby H₂S stimulates *Mtb* respiration. In a previous study²², our findings in *M. smegmatis* and *Mtb* implicate cytochrome *bc₁/aa₃* and cytochrome *bd* in enhancing respiration when exposed to H₂S, primarily because the *Mtb* electron transport chain (ETC) can rapidly reroute electrons to either of these oxidases (Fig. 5i). To investigate whether Cys-generated H₂S regulates respiration through cytochrome *bc₁/aa₃* and/or cytochrome *bd* (CytBD), we examined Δ *cydAB* cells (genetic knockout of *Mtb* *cytBD*) in the presence of Cys and the cytochrome *bc₁/aa₃* inhibitor Q203. Hence, the Δ *cydAB* strain of *Mtb* produces only a functional cytochrome *bc₁/aa₃*⁴⁷, and cellular respiration can be fully inhibited by Q203⁴⁶. Intriguingly, both WT *Mtb* (Fig. 5j) and Δ *cydAB* cells (Fig. 5k) show increased respiration when exposed to Cys, suggesting that H₂S stimulates *Mtb* respiration via cytochrome *bc₁/aa₃* oxidase. However, *Mtb* cells treated with the cytochrome *bc₁/aa₃* oxidase inhibitor Q203 and Cys showed a more profound increase in respiration (OCR% ~330; Fig. 5l) compared to Δ *cydAB* cells (OCR% ~145; Fig. 5k) at 1 mM Cys. This suggests that Cys-generated H₂S stimulates *Mtb* respiration more strongly through cytochrome *bd* compared to cytochrome *bc₁/aa₃* oxidase. As expected, respiration was dramatically reduced when Δ *cydAB* cells were exposed to Q203 alone, or Q203 and Cys (Fig. 5m). While recognizing that the precise mechanism whereby H₂S stimulates *Mtb* respiration is complex, these data provide strong evidence that Cds1 uses Cys as a source of sulfur to produce H₂S, which modulates *Mtb* respiration predominantly via CytBD.

***Mtb* H₂S regulates sulfur metabolism**

Our data demonstrate that Cds1 is a cysteine desulfhydrase that generates H₂S from Cys (Fig. 2f). Hence, Cds1 may serve to eliminate toxic levels of Cys, which can induce oxidative stress via the Fenton reaction^{9,48}. Not surprisingly, Cys can be rapidly oxidized to cystine (the disulfide form of Cys; Cys_{ox})⁴⁹. Overall, the enzymatic properties of Cds1 are

consistent with our data showing that $\Delta cds1$ cells exhibit reduced growth in medium containing toxic concentrations of Cys (Fig. 3f). To test the hypothesis that Cds1-generated H_2S regulates cellular sulfur metabolism, we performed carbon tracing experiments using [U- ^{13}C]-Cys (100 μM in 7H9 medium; capable of inducing H_2S production [Supplemental Fig. 1]), to track the fate and incorporation of Cys carbons into metabolites. We subsequently examined metabolite abundance and the carbon isotopologue distribution (CID) of targeted sulfur metabolites (Fig. 6a-g) in WT *Mtb*, $\Delta cds1$, and *comp* cells.

We observed an overall increase in the abundance of sulfur pathway metabolites cystathionine (Cth), O-succinyl homoserine (OSH), homoserine (Hse), homocysteine (Hcy), Met, Cys and Cys_{ox} in $\Delta cds1$ cells (Fig. 6a-g). A likely explanation for the build-up of these sulfur metabolites is that sulfur atoms cannot be dissipated via Cds1-mediated release of H_2S , thereby generating back pressure and a subsequent metabolite build-up. Exogenous [U- ^{13}C]-Cys was rapidly converted into Cys_{ox}, which accumulates significantly more in $\Delta cds1$ cells (Fig. 6a) compared to the controls, due to the lack of Cds1 activity and a subsequently impaired capacity to recycle sulfur atoms via CysK1 and O-acetyl serine (OAS) back to Cys (Fig. 6b). In $\Delta cds1$ cells, most of the carbons in Cys are unlabelled (Fig. 6b), which suggests that most carbons for *de novo* synthesis of Cys originated from glucose or glycerol, leading to a small, but significant increase in unlabeled Cys. Lastly, the significant changes in CID of M+5 and M+6 species in the OSH metabolite pool and increased abundance of Cth (Fig. 6c), OSH (Fig. 6d), Hse (Fig. 6e) are indicative of reduced flux of [U- ^{13}C]-Cys carbons in the sulfur pathway leading to the subsequent build-up in $\Delta cds1$ cells. Notably, Hcy was almost completely labeled, pointing to the importance of this metabolite in the Cys–Cth conversion step, and anabolism of Hcy via MetC (Fig. 6g).

To complement our [U- ^{13}C]-Cys results, in an independent experiment, we used [U- ^{13}C]-glucose as the carbon tracer. The rationale for using labeled glucose is twofold; firstly, unlike [U- ^{13}C]-Cys, this approach allows us to trace the incorporation of glucose-derived carbons into sulfur metabolites. Secondly, it will allow us to trace incorporation of glucose carbons into *de novo* synthesized Cys, which is a substrate for H_2S production in the absence of an exogenous substrate. Importantly, similar to our [U- ^{13}C]-Cys results (Fig. 6a-g), we also observed an accumulation of sulfur pathway metabolites (e.g., Cys, cystathionine, O-succinyl homoserine, homoserine, and Met) in $\Delta cds1$ cells compared to WT and *comp* (Fig. 6h-m). Hence, the [U- ^{13}C]-glucose tracing data complement our Cys carbon tracing data (Fig. 6a-g) as they show that *de novo* synthesis of Cys is required for H_2S production, which is not possible to demonstrate using [U- ^{13}C]-Cys, since it is a substrate for H_2S production (Supplemental Fig. 1). Intriguingly, all Cys carbons were unlabeled and Cys showed increased abundance in $\Delta cds1$ cells (Fig. 6i), suggesting that >50% of Cys_{ox} carbons originated from glucose whereas most of the Cys carbons originated from glycerol

when cultured in 7H9 medium containing [U-¹³C]-glucose and glycerol. Increased accumulation of Hse was noted in $\Delta cds1$ cells despite reduced flux, which was evident by an increase in CID of M+0 species and decreases in CID of M+1, M+2 and M+3 species (Fig. 6l).

In summary, these data demonstrate that Cds1 is important for maintaining homeostatic levels of sulfur pathway metabolites through the production of H₂S, which allows recycling of sulfur atoms back to Cys and metabolites in the sulfur pathway. Lack of Cds1 activity triggers metabolic dysregulation of key sulfur pathway metabolites as is evident by the corresponding build-up of Cys, Cys_{ox}, Cth, OSH, Hse, Hcy, and Met. Hence, our data suggest that Cds1-generated H₂S functions as a sink to maintain sulfur homeostasis.

***Mtb* H₂S regulates central metabolism**

There is a surprising lack of targeted metabolomic studies of sulfur metabolism in bacteria, as we could identify only two such studies that focus on sulfur metabolism^{50,51}. Both studies showed that different sulfur fuel sources affect glycolysis, the TCA cycle, amino acid levels, and redox couples such as glutathione and mycothiol (MSH). Since we have shown that Cds1/H₂S modulates growth (Fig. 3f) and respiration (Fig. 5c and 5g), which is tightly linked to metabolism, we tested the hypothesis that Cds1-generated H₂S modulates *Mtb* central metabolism. To test this hypothesis, we cultured WT *Mtb*, $\Delta cds1$ and *comp* cells in 7H9 medium containing [U-¹³C]-Cys and examined metabolites in glycolysis, the pentose phosphate pathway (PPP), TCA cycle, and all amino acids (Fig. 7). A striking observation was the significant increase of most amino acids (Fig. 7a), glycolytic metabolites, PPP metabolites (6-phosphogluconate [6PG] and ribulose-5-phosphate [R5P]), and TCA intermediates in $\Delta cds1$ cells compared to WT and *comp* cells (Fig. 7b), which strongly suggests that H₂S plays a key role in modulating central metabolism. Importantly, we observed a similar, and significant increase of amino acids in $\Delta cds1$ cells compared to WT and *comp* cells using [U-¹³C]-glucose as the carbon tracer (Supplementary Fig. 13). This was not entirely unanticipated as endogenous (Fig. 5g) and exogenous H₂S regulate respiration (OXPHOS) in *Mtb*²². Also, H₂S directly targets enzymes in the glycolytic pathway through persulfidation to modulate their activity^{52,53} and was shown to suppress glycolysis in *Mtb*-infected macrophages²³. The overall reduced labeling of amino acids and glycolysis/TCA cycle metabolites in $\Delta cds1$ cells is consistent with the concept that these metabolites obtain their carbons mainly from glucose or glycerol, and not Cys. We observed a similar accumulation of sulfur pathway metabolites. On the other hand, F16BP and PEP were substantially labeled (~50%) in all three strains, which are the product and substrate of the first and last rate-limiting steps in glycolysis, respectively. This points to phosphofructokinase-1 (Pfk1) and pyruvate kinase (PykA) as important rate-limiting flux

control points for the metabolism of Cys carbons into central metabolism. Further, to ascertain whether increased glycolytic and TCA metabolites translate into changes in ATP levels, we quantified ATP in cells with or without Cys (100 μ M). As shown in Fig. 7c, ATP levels were significantly increased in $\Delta cds1$ cells cultured with Cys, whereas no difference in ATP level was observed in the absence of Cys.

In summary, our targeted metabolomics data demonstrate that Cds1-generated H_2S suppresses central metabolism, which is evident by increased levels of glycolytic and TCA cycle metabolites and amino acids in $\Delta cds1$ cells. Also, the reduction in H_2S levels in $\Delta cds1$ cells, which is associated with decreased respiration (OXPHOS) (Fig. 5a), triggers a compensatory glycolytic response to maintain bioenergetic homeostasis as was evident by increased ATP levels in $\Delta cds1$ cells. Collectively, our data demonstrate that endogenous H_2S functions as a modulator of the balance between OXPHOS and glycolysis in *Mtb*.

Endogenous H_2S exacerbates oxidative stress and regulates intracellular redox homeostasis

Several studies have reported a role for H_2S in the modulation of redox homeostasis⁵⁴⁻⁵⁶. In *E. coli*, endogenously produced H_2S maintains redox homeostasis by rendering *E. coli* resistant to oxidative stress¹⁴. Hence, we tested the hypothesis that Cds1-generated H_2S modulates redox homeostasis in *Mtb* by measuring the abundance and flux of the two major redox couples ergothioneine (EGT) and mycothiol (MSH) via metabolomics, and by quantifying reactive oxygen intermediates (ROI) by flow cytometry²². Since catalase is present in standard 7H9 growth medium to protect cells against toxic peroxides and promote growth, we examined the levels of ROI in *Mtb* cells (Supplementary Fig. 14) in the presence and absence of catalase. In medium containing catalase, we observed ~43% more ROI-positive $\Delta cds1$ bacilli compared to WT and *comp* (Fig. 8a), suggesting that in WT *Mtb*, H_2S may function as an antioxidant, as has been reported in mammalian cells¹⁸. In the absence of catalase, the percentage of ROI-positive cells increased by 4-10-fold in all strains compared to cells in the presence of catalase (Fig. 8a). Of note, ~25% fewer $\Delta cds1$ bacilli were ROI-positive compared to WT or *comp* cells, suggesting that H_2S functions as a pro-oxidant under these conditions.

Next, since Cys is a sulfur-containing precursor of MSH and EGT, we examined the abundance and CID of these redox couples in $\Delta cds1$ cells cultured in 7H9 medium containing [U-¹³C]-glucose (Fig. 8b). Intriguingly, EGT and MSH levels were reduced in $\Delta cds1$ cells. Further, the increase in the CID of M+1, M+2, M+3, M+4, and M+1 and M+2 species in EGT and MSH, respectively, suggests increased carbon scrambling and reduced flux of carbons in response to the failure to recycle H_2S back to Cys in $\Delta cds1$ cells. This agrees with the lack of increase of fully labeled species of EGT (M+9) and MSH (M+17).

Therefore, our data demonstrate that H₂S is necessary for maintaining homeostatic levels of MSH and EGT, and thus redox balance. To further examine the role of H₂S in *Mtb* redox homeostasis, we exposed *Mtb* to the oxidant cumene hydroperoxide (CHP) without catalase and monitored ROI production and cell viability. After 16 hours of exposure to 0.25 mM CHP, $\Delta cds1$ cells had significantly fewer ROI-positive cells (Fig. 8c) with increased survival (Fig. 8d) compared to WT and *comp* cells. Notably, we observed no significant differences in the abundance of MSH or EGT between WT, *comp* and $\Delta cds1$ cells after exposure to CHP (Supplementary Fig. 15).

Collectively, these data show that H₂S can function either as a pro-oxidant or antioxidant depending on the experimental conditions. Further, the survival data indicate that reduced homeostatic levels of H₂S promote survival during oxidative stress in the absence of catalase. Hence, under oxidative stress conditions, endogenously produced H₂S in *Mtb* functions as a pro-oxidant. Lastly, our data demonstrate that Cds1-generated H₂S modulates the levels of the major redox couples, EGT and MSH.

Endogenous H₂S increases *Mtb* susceptibility to clofazimine (CFZ) and rifampicin (RIF)

H₂S has been shown to alter antibiotic susceptibility in several bacterial pathogens including *E. coli*, *Bacillus anthracis*, *Pseudomonas aeruginosa* and *Staphylococcus aureus*^{14,15}. Hence, understanding the impact of endogenous H₂S on *Mtb* drug susceptibility may have clinical implications. We posited that Cds1-generated H₂S modulates susceptibility to the anti-TB drug clofazimine (CFZ), a known ROI generator⁴⁶. After 24 hours of CFZ exposure at 60x MIC, ~30% fewer $\Delta cds1$ cells were ROI-positive compared to WT or *comp* cells (Fig. 8e). Further, we observed significantly increased CFU-based survival of $\Delta cds1$ versus WT control cells after 8 days of CFZ exposure (Fig. 8f). These differences in survival between $\Delta cds1$ and WT and *comp* strains exposed to CFZ were significant, albeit modest, which may be due to the fact that H₂S production was reduced, but not eliminated, in $\Delta cds1$ cells (Fig. 3d). Hence, genetic knockout of multiple genes involved in H₂S biosynthesis may further decrease *Mtb* sensitivity to CFZ. Regardless, these CFZ-exposure data indicate that endogenous H₂S increases ROI in WT *Mtb* that contributes to CFZ susceptibility.

Exogenous H₂S has been shown to modulate antibiotic susceptibility in a range of bacterial pathogens^{14,15,18,54}. To determine whether exogenous H₂S plays a role in *Mtb* drug susceptibility, CFZ-treated *Mtb* cells were exposed to H₂S via addition of NaHS. Exogenous H₂S significantly reduced survival of CFZ-treated *Mtb* cells (Fig. 8g and h). Likewise, *Mtb* cells treated with rifampicin (RIF) or isoniazid (INH) for five days were exposed to exogenous H₂S. As shown in (Fig. 8i), H₂S significantly increased susceptibility to RIF, but not to INH.

In summary, these data suggest that H₂S increases *Mtb* susceptibility to CFZ and RIF through its function as a pro-oxidant.

Discussion

This study elucidates several previously unrecognized physiological features of *Mtb*. Using three different methods, we have shown that laboratory and MDR and DS clinical *Mtb* strains produce H₂S, as do non-pathogenic slow- and fast-growing mycobacterial strains. We then identified the genetic locus *cds1* (*rv3684*) and confirmed that the gene product, Cds1, is a PLP-dependent H₂S-producing enzyme. Importantly, we demonstrate that endogenous H₂S can influence *Mtb* bioenergetics by enhancing respiration, primarily via CytBD, and modulating the balance between respiration (OXPHOS) and glycolysis. Further, we describe a plausible mechanism by which *Mtb* mitigates oxidative stress by converting excess Cys into H₂S, which is released and then recycled. Our findings point to a paradigm whereby *Mtb*-generated H₂S, together with host-generated H₂S, exacerbates TB disease by dysregulating host immunity²³. Lastly, since H₂S production by *Mtb* has been an overlooked confounder in routine culturing of *Mtb*, we anticipate our findings to have a broad practical impact in the TB field.

Since the discovery of *Mtb* by Robert Koch in 1882, formal proof that *Mtb* produces H₂S has been lacking. One likely reason is that since *Mtb* is highly contagious and spread through aerosols, smelling of cultures is a significant health risk and extreme measures are taken to avoid inhalation. Nonetheless, several biochemical studies²⁵⁻²⁹, as well as homologues of H₂S-producing enzymes in the *Mtb* genome have provided strong circumstantial evidence that *Mtb* is a likely producer of H₂S. Furthermore, complicating factors are that H₂S is a difficult molecule to study because measuring it is complex⁶, and that H₂S can be spontaneously generated from media components⁸. Hence, we employed multiple approaches to provide compelling evidence that *Mtb* produces H₂S.

Our findings that two clinical MDR *Mtb* strains produce the highest levels of H₂S, followed by laboratory strains and clinical DS strains, have considerable clinical importance for several reasons. Firstly, many clinical MDR and XDR *Mtb* strains are notoriously difficult to culture due to extremely slow growth. Since high concentrations of H₂S inhibit respiration^{20,57}, it is not unreasonable to propose that excessive H₂S production contributes to the slow growth of many of these strains, even when cultured in the absence of Cys. Secondly, our findings that endogenous levels of H₂S suppress central metabolism suggest that excessively high levels of H₂S produced by MDR *Mtb* strains could reprogram metabolism by shifting the balance between OXPHOS and glycolysis, ultimately leading to an energetically impaired state that inhibits growth. Thirdly, the large variation in H₂S production among clinical strains likely reflects functional differences that are due to SNPs or

genomic rearrangements that contribute to strain-specific transcriptional regulation. Lastly, since H₂S is widely used as a diagnostic test for bacteria, there is potential for the development of H₂S-based diagnostics for *Mtb*, e.g., detection of H₂S in the exhaled breath or sputum of TB patients.

How do these findings contribute to a more accurate understanding of *Mtb* physiology and pathogenesis? In two recent studies, it was shown that host-derived H₂S exacerbates *Mtb* disease in the mouse model of TB^{22,23}, and that CSE and 3MST protein levels are markedly increased in human TB lesions that surround necrotic granulomas and cavities²³. Hence, it was proposed that because of the strong immunomodulatory activity of H₂S, excessive host H₂S production triggered by *Mtb* infection dysregulates immunity to promote disease²³. Considering the findings in this study, we posit that *Mtb*-generated H₂S may act as a signalling molecule in the host, further contributing to excessive H₂S levels *in vivo* to exacerbate disease. This is possible since Cys concentrations range from ~128 - 250 μM in human cells and plasma^{58,59}. Although a role for *Mtb* *cds1* in TB disease has not yet been reported, our genetic knockout (Fig. 3d) and other data (Supplementary Table 1) indicate that more than one enzyme contributes to H₂S production in *Mtb*. Therefore, multiple gene knockouts may be necessary to convincingly demonstrate a role for endogenously-produced H₂S in TB disease.

Discovery of a gene responsible for H₂S production in *Mtb* cells establishes a paradigm for how H₂S modulates *Mtb* physiology. While homologues of CBS and CSE are encoded in the *Mtb* genome, these proteins were not identified in our non-denaturing in-gel BC assays. However, this could be explained by the fact that the conditions of our in-gel BC assay were suboptimal for certain enzymes, and that alterations in environmental factors (substrate, pH, temperature, oxygen, etc) or redox-dependant cofactors (e.g., NADH, NADPH, heme), would allow detection of additional enzymes.

Based on our cell-based assays, Cds1 contributes significantly to H₂S production and showed increased activity when cells are exposed to Cys. Since the total sulfur atom concentration in bacteria (e.g., *E. coli*) is ~130 mM and intracellular Cys serves as the primary supplier of sulfur atoms⁴⁴, it is possible that Cds1 shuttles sulfur atoms between metabolites to meet cellular demand and to maintain redox balance. Indeed, Cds1 protects *Mtb* and *Msm* against toxic concentrations of Cys, providing insight into the mechanisms whereby Cds1 mitigates intracellular oxidative stress triggered by Cys, which feeds the Fenton reaction to generate free radicals⁹. Therefore, our data (Figs. 3f, 6, and 7) support the concept that the Cds1-mediated conversion of Cys into H₂S functions as a sink for excess Cys. This concept is further supported by studies showing that high levels of Cys inhibit growth⁶⁰, induce ROI production, and lead to DNA damage in *E. coli*⁹ and *Mtb*⁴⁸.

Like other small nonelectrolytes such as •NO, CO, and O₂, at a gas/liquid interface H₂S in solution (as a dissolved solute) readily “escapes” solvation and volatilizes. Likewise, as a gas at this interface, it will readily dissolve and so with a confined headspace a dynamic equilibrium of volatilization/dissolution will exist, defined quantitatively by Henry’s Law. As pointed out elsewhere¹⁸, the ability of H₂S to exist as a gas has functional biological relevance only in the presence of such a gas/liquid interface, which is also true for •NO, CO, and O₂⁶¹. As demonstrated previously⁶², the contribution of volatilization *in vitro* will be determined by the specific experimental configuration. In the lung, where such an interface is central to organ function, the “headspace” is not confined. Therefore, according to Le Chatelier’s principle the process of ventilation will serve to pull this equilibrium in the direction of volatilization and therefore may well serve to amplify the importance of desulfhydration as a sink for H₂S (and its conjugate bases HS⁻ and S²⁻) *in vivo*. The relative importance of volatilization as a sink will depend on its magnitude compared to other competing mechanisms of consumption in the organism and tissue⁶³.

Our finding that Cds1 generates H₂S and pyruvate using Cys as substrate suggests that Cds1 is catalytically similar to mammalian and bacterial CSE, which converts Cys into H₂S, pyruvate and ammonia¹⁹. Elegant biochemical studies have shown that *Mtb* Rv1079 possess both CSE and cystathionine γ-synthase (CGS) activity²⁶. However, Rv1079 lacks Cys desulfhydrase activity and these authors speculated that an as yet uncharacterized enzyme performed this important role²⁶. We provide genetic and biochemical evidence that Cds1 fulfils this function through its Cys desulfhydrase activity, which adds to our understanding of how *Mtb* detoxifies Cys.

An unusual feature of H₂S is its ability to stimulate bioenergetics at low concentrations and inhibit respiration at higher concentrations. In a recent study, we demonstrated that low concentrations of exogenous H₂S stimulate *Mtb* respiration and growth²². In mammals, H₂S has been implicated in reversibly inhibiting cytochrome c oxidase (Complex IV) at high concentrations, and conversely, stimulating mitochondrial respiration at low concentrations^{20,21,64,65}. Our finding that Cds1-generated H₂S is an effector molecule that modulates basal respiration reveals a previously unknown facet of *Mtb* physiology. This is supported by genetic and bioenergetic data showing a ~40% reduction in the basal respiration of Δ *cds1* cells compared to WT *Mtb*.

By exploiting a *Mtb* *cytBD* mutant and pharmacological inhibition of cytochrome *bc₁/aa₃*, our findings provide insight into how H₂S can stimulate respiration. Contrary to studies in *E. coli* that show cytochrome *bo₃* oxidase is susceptible to H₂S and its two *bd* oxidases are resistant to H₂S^{44,45}, our current data suggest that Cys-generated H₂S stimulates respiration via both *Mtb* cytochrome *bc₁/aa₃* and CytBD, consistent with our previous findings²². For example, in the presence of Cys, respiration is dramatically

increased when cytochrome *bc₁/aa₃* oxidase is inhibited with Q203 compared to respiration in the *Mtb* *cytBD* mutant. Hence, CytBD plays a more prominent role than cytochrome *bc₁/aa₃* in H₂S-mediated stimulation. Determining whether H₂S directly binds to one or both oxidases in *Mtb* to stimulate respiration will require further investigation. *Mtb* and *E. coli* respond differently to H₂S, likely because they occupy vastly different niches. *Mtb* is an obligate aerobe that colonizes the human lung whereas *E. coli* is a facultative anaerobe and ubiquitous member of the human gut microbiota that is exposed to millimolar concentrations of H₂S. More importantly, unlike other bacteria, *Mtb* has the unusual ability to rapidly reroute ETC flux to either cytochrome *bc₁/aa₃* or CytBD⁴⁶ depending on which oxidase is inhibited. This remarkable plasticity allows *Mtb* to effectively respond to host gases such as NO and CO which inhibit respiration, and H₂S, which can stimulate respiration.

Respiration is directly linked to central metabolism, and not surprisingly, Cds1-generated H₂S suppresses glycolysis in WT *Mtb* as was evident by increased levels of numerous glycolytic metabolites in Δ *cds1* cells. We propose two plausible mechanisms whereby H₂S could modulate the balance between OXPHOS and glycolysis (Fig. 8j): Firstly, reduced respiration (OXPHOS) in Δ *cds1* cells triggers a compensatory glycolytic response, *i.e.*, substrate level of phosphorylation to meet the bioenergetic demands for ATP. This is not an unusual metabolic response, as it was previously posited that bedaquiline-mediated inhibition of OXPHOS leads to a compensatory induction of glycolysis to meet the demand for ATP through substrate level phosphorylation^{46,66}. Also, recent studies in *Bacillus* and *Staphylococcus* spp. showed that glycolysis can reverse polymyxin B-mediated ATP depletion that resulted from dysregulation of OXPHOS^{67,68}. Secondly, H₂S can directly target enzymes in the glycolytic pathway through persulfidation to modulate their activity^{52,53}. This is supported by recent studies showing that H₂S suppresses glycolysis in macrophages upon *Mtb* infection²³.

Respiration and central metabolism are also linked to redox balance (via MSH and EGT) and ROI production in bacteria⁶⁹, and we demonstrated that Cds1-generated H₂S plays a role in maintaining *Mtb* redox homeostasis. Our data show that catalase in growth media influences ROI production, and that H₂S can function as a oxidant or reductant depending on the environmental conditions. In this regard, careful consideration should be given to experimental design and subsequent conclusions since exogenous catalase in 7H9 medium is widely known to influence INH drug susceptibility and is routinely excluded from medium in INH susceptibility studies. It has been suggested that 3MST-derived H₂S protects *E.coli* against oxidative stress via H₂S-mediated sequestration of Fe²⁺¹⁴. In *Mtb*, exogenous H₂S upregulates key members of the copper regulon, suggesting that copper, which has a high affinity for H₂S, may contribute to increased ROI when exposed to excess H₂S²².

The unusual effect of H₂S on *Mtb* respiration and oxidative stress as demonstrated in this study, as well as previous studies on how H₂S impacts antibiotic resistance¹⁵, guided us toward considering a role for H₂S in the cellular response to anti-TB drugs such as CFZ, which kills *Mtb* via ROI production⁷⁰. Indeed, our data demonstrate that H₂S exacerbates oxidative stress in the presence of CFZ. Not surprisingly, $\Delta cds1$ cells are more resistant to CFZ, consistent with our data showing that addition of exogenous H₂S to CFZ-treated cells increases *Mtb* killing. On this basis, we propose that endogenous H₂S stimulates respiration leading to increased ROI production that synergizes with ROI produced by CFZ, ultimately increasing killing. Whereas previous studies have shown that addition of Cys to *Mtb* cells increases respiration and killing of *Mtb* persists treated with INH and RIF⁴⁸, our study suggests that H₂S could be the effector molecule in that model. It should be recognized that exogenous Cys also generates H₂O₂ to trigger the Fenton reaction, which leads to continuous OH• formation that damages DNA which may exacerbate the effect of INH, particularly in closed vessels where H₂O₂ accumulates⁴⁹. Exogenous H₂S in combination with RIF also increased *Mtb* killing, likely because RIF also generates oxidative stress⁷¹, but this effect was less pronounced. These findings may have important implications for TB therapy, as they suggest that sulfur sources *in vivo* could influence anti-TB drug efficacy. Similarly, recent studies have shown that exogenous H₂S with RIF (and other antibiotics) confer hypersensitivity to *Acinetobacter baumannii*⁷².

Overall, our findings represent a significant conceptual advance that may broadly impact the TB field, especially since H₂S production by *Mtb* is a previously overlooked confounding factor in routine TB experimentation. Our findings present a basis for understanding how *Mtb*-derived H₂S regulates *Mtb* OXPHOS and glycolysis, redox homeostasis, and anti-TB drug susceptibility. These findings may also contribute to original virulence paradigms whereby host- and *Mtb*-generated H₂S subverts host immunity. Lastly, we anticipate that our findings will contribute to a fresh understanding of phenotypic variation in clinical strains of *Mtb* as well as novel diagnostics based on H₂S production.

Materials and Methods

General

All mycobacteria strains were cultured in Middlebrook 7H9 media (Difco) supplemented with 0.01 % tyloxapol (Sigma), 0.2 % glycerol (Sigma) and 10% (oleic acid, bovine albumin fraction V, dextrose, and catalase [OADC]) unless stated otherwise. Cultures were placed in a shaking incubator (100 rpm) at 37 °C. Strains examined included *Mb* H37Rv, *Mtb* CDC1551, *Mycobacterium bovis* (supplemented media with 100 µM sodium pyruvate), *Mycobacterium bovis* BCG, *M. smegmatis*, two drug susceptible *Mtb* strains (TKK-01-0027 and TKK-01-0047) and two multi-drug resistant *Mtb* strains (TKK-01-0035 and TKK-01-0001). The drug MIC₅₀ values used during this study were as follows: Clofazimine (CFZ), 211 nM; Rifampicin (RIF), 486 nM; Isoniazid (INH) 240 nM. Where required, the following antibiotics were used; hygromycin B (100 µg/ml for *E. coli*, 50 µg/ml for mycobacteria) and kanamycin (50 µg/ml for *E. coli*, 25 µg/ml for mycobacteria). Dihydroethidium (DHE) was purchased from Thermo Fisher Scientific (Cat# D11347). Restriction enzymes were obtained from Thermo Scientific (Germany). KOD Xtreme Hotstart DNA polymerase kit was obtained from Merck (Darmstadt, Germany). T4 DNA ligase was obtained from New England Biolabs (NEB). *E. coli* DH5α, used for cloning and DNA manipulation, was routinely cultured in Luria-Bertani liquid media at 37 °C. Oligonucleotides were synthesized by Thermo (USA). All other reagents were purchased from Merck or Sigma-Aldrich.

Preparation of mycobacterial lysates

All cultures were grown to an OD₆₀₀ of ~0.8. The cells were then harvested from 30 ml of culture and centrifuged at 4,000 x g for 5 min. The supernatant was discarded, and the pellet was resuspended in 1-2 ml of lysis buffer (50 mM Tris-HCl, pH 8.0; 150 mM NaCl; protease inhibitor [Roche]), depending on the size of the cell pellet. Cells were lysed in a Magnalyser (Roche) at 7000 rpm for 1 min and then placed on ice for 4 min. This was repeated 3-4 times. The lysates were then centrifuged at 15,000 x g for 10 min. The supernatant was collected and passed through a 0.22 µm filter. Protein concentrations were determined using the Micro BCA Protein Assay Kit (Thermo Fisher Scientific) and the absorbance at 562 nm was measured using a Biotek Synergy H4 Hybrid plate reader. Lysates were stored at -80 °C until use.

H₂S measurement using the lead acetate assay

Mycobacterial cultures were harvested at an OD₆₀₀ of 0.8-1 and centrifuged at 3,500 x g for 5 min. The bacterial pellet was resuspended in an equal volume of 7H9 media containing 0.01% tyloxapol, 0.2% glycerol and 10% OADC. 10 ml of diluted culture at an OD₆₀₀ of 0.1

was then transferred to a 30 ml culture bottle. Lead acetate strips (Thermo Fisher Scientific) were affixed to the inner wall of the culture bottles. The strips were monitored for the formation of dark colored lead sulfide precipitate and scanned after 48 h. The intensity of the dark lead sulfide stain is proportional to the amount of H₂S present. The lead sulfide stain was then scanned and quantified by measuring the grayscale values for a specific area of each strip and normalized to OD₆₀₀ using ImageJ software version 1.53a (Java 1.8.8_12 (64 bit))³⁴.

H₂S measurement using the bismuth (III) chloride (BiCl₃) assay

The BiCl₃ (BC) assay is used to measure H₂S based on the reaction of H₂S with a bismuth (III) salt to form bismuth (III) sulfide (Bi₂S₃), which appears as a brown-to-black precipitate³¹. The microplate BC assay was performed in 96-well plates using intact H37Rv bacteria and lysates as described by Basic, *et al.* (2015)³⁰. Once the OD₆₀₀ of cultures reached ~0.8-1, the cultures were centrifuged at 3500 x g for 5 min. The supernatant was discarded, and the culture pellet was resuspended in the original volume of media before centrifugation. The BC assay solution (2x) contains 0.4 M triethanolamine-HCl/Tris-HCl (Sigma), pH 8.0; 1 mM BiCl₃ (Sigma); 20 μM pyridoxal 5-phosphate monohydrate (PLP) (Sigma), 20 mM EDTA (Sigma) and 40 mM L-cysteine (Cys) (Sigma). 100 μl of the mycobacteria cell suspension (OD₆₀₀ = 1.0) or lysate (5 μg), with or without the inhibitors AOAA and PAG were mixed with 100 μl of freshly prepared 2x bismuth solution in clear flat-bottomed 96-well microtiter plates (Costar). For H₂S measurements when *Mtb* was grown on different carbon sources, 100 μl of mycobacterial cell suspension in 7H9 medium containing 0.01% tyloxapol was supplemented with either: 0.4% glycerol, 1 mM sodium butyrate (Sigma), 8 mM sodium acetate (Sigma), 2 mM sodium propionate (Sigma) or 0.02% (wt/vol) cholesterol (Sigma). These cell suspensions were then mixed with 100 μl of freshly prepared 2x bismuth solution in clear flat-bottomed 96-well microtiter plates (Costar). The working stock cholesterol was initially dissolved at 100 mg/ml in a solution of tyloxapol:ethanol (1:1) at 80° C. Bi₂S₃ formation was determined by measuring the absorbance at 405 nm. The kinetics for mycobacterial cells was measured every 30 min for 15-20 h at 37 °C with shaking using a Hidex Sense Plate reader. Enzymatic kinetics using lysates was measured every 5 min for 5-20 h, with shaking at room temperature (~20–22 °C) using a Biotek Synergy H4 Hybrid Reader.

***Mtb* growth in fatty acids or cholesterol as the sole carbon source**

One hundred microliters of mycobacterial cell suspension of OD₆₀₀ ~0.1 in 7H9 containing 0.01% tyloxapol was mixed with 100 μl of 7H9 media containing 0.01% tyloxapol supplemented with either: 0.4% glycerol, 1 mM sodium butyrate, 8 mM sodium acetate, 2

mM sodium propionate, or 0.02% (wt/vol) cholesterol in clear flat-bottomed 96-well microtiter plates. The plates were placed in an incubator at 37 °C. OD₆₀₀ measurements were taken after 7 days.

H₂S measurement using the Unisense amperometric microsensor

H₂S released by cell cultures and lysates was measured at room temperature, with a sensitive sulfide amperometric microsensor, H₂S-500 (Unisense, A/S, Denmark) connected to a microsensor multimeter (Unisense, A/S, Denmark) as an amplifier for data acquisition. The signal for H₂S was collected in mV and converted to μM using a NaHS (Thermo Fisher Scientific) standard curve generated from a concentration range of 0 to 100 μM (freshly prepared in an anaerobic glovebox). The H₂S microsensor was calibrated in accordance with the manufacturer's instructions. Bacteria at an OD₆₀₀ of 0.2 were cultured in media with or without 1 mM Cys. After 72 h, H₂S concentrations were measured using the microsensor in the cell culture and the cell-free culture supernatants (referred to as 'cleared supernatants').

For real-time H₂S measurement in lysates, the microsensor was placed in a 2 ml tube containing 1 ml assay buffer (0.4 M triethanolamine-HCl, pH 8.0; 20 μM PLP, 10 mM EDTA) with or without 20 mM Cys. The signal was allowed to stabilize for 2-5 min after which 40 μg *Mtb* lysate was added to the reaction. When appropriate, Cys (0.1 to 4 mM) was subsequently added to the tube at different time intervals. To confirm AOAA inhibition, *Mtb* lysate preincubated with AOAA (4 mM) was added to the assay buffer containing 20 mM Cys. OASS activity was measured by placing the microsensor in 1 ml PBS solution. A 10 μl aliquot of 25 mM NaHS was added to the reaction tube twice and after the signal stabilized, 30 ng of OASS was added to the reaction. After 2 min, OAS was added to the reaction to a final concentration of 10 mM and the H₂S signal monitored in real time.

Native PAGE analysis and in-gel BC assay

Equal amounts (15-25 μg per lane) of mycobacterial lysate were resolved on 10% PAGE gels (Bio-Rad) under non-denaturing conditions using running buffer containing 25 mM Tris-base and 190 mM glycine. To detect the presence of H₂S-producing proteins, gels were incubated in 20-50 ml of BC solution and incubated at room temperature with shaking. Gels were monitored every 20-60 mins for the appearance of dark-colored Bi₂S₃. For gels exposed to AOAA, gels were incubated in 20 ml of 2 mM AOAA in 50 mM Tris-HCl pH 8.0 with shaking at room temperature for 5 mins, followed by BC solution containing 2 mM AOAA overnight.

Extracellular Flux analysis

The oxygen consumption rates (OCR) of *Mtb* strains were measured using a Seahorse XF96e Extracellular Flux Analyzer (Agilent). *Mtb* bacilli were adhered to the bottom of a Cell-Tak-coated XF cell culture microplate at 2×10^6 bacilli per well. Cell-Tak has no effect on *Mtb* basal respiration⁴⁶. Assays were carried out in unbuffered 7H9 media (pH 7.35) with no carbon source. *Mtb* bacilli were grown in this unbuffered 7H9 media, containing only 0.01 % Tyloxapol, for 24 h before being seeded into the XF cell culture microplate at the start of the experiment. In general, basal OCR was measured for ~25 min before automatic sequential injection of various compounds through the drug ports of the sensor cartridge. The duration of OCR measurements after compound addition, and the concentrations used, varied by experiment. OASS modulation of *Mtb* OCR in the presence of Cys was performed by the simultaneous addition of Cys, OASS and substrate OAS (final concentration of 4 mM, 0.03 µg/ml and 4 mM, respectively). Q203-based modulation of the OCR in *Mtb* and $\Delta cydAB$ cells was performed in the presence of the indicated Cys concentration followed by addition of Q203 (300x MIC₅₀; MIC₅₀ for Q203 is 3 nM)⁴⁶. To chemically complement $\Delta cds1$ cells with H₂S, different concentrations of NaHS were added to cells after measuring the baseline OCR. All OCR data figures indicate the time of each addition as dotted lines. OCR data points are representative of the average OCR during 4 min of continuous measurement in the transient microchamber, with the error being calculated from the OCR measurements taken from at least three replicate wells by the Wave Desktop 2.2 software (Seahorse Biosciences). The transient microchamber is automatically re-equilibrated between measurements through the up and down mixing of the probes of the XF96 sensor cartridge in the wells of the XF cell culture microplate.

CFU-based assay

Mid-log phase mycobacterial cultures were diluted to an OD₆₀₀ of 0.01 in 7H9 media. For survival studies in the presence of NaHS, bacterial cultures (7H9 with 10 % OAD) were untreated or treated with anti-TB drugs and NaHS at indicated concentrations. For survival studies in the presence of antioxidants, bacterial cultures (7H9 with 10 % OAD) were treated with or without 0.25 mM cumene hydroperoxide (CHP) for 16 h. For survival studies in the presence of CFZ, bacterial cultures (7H9 with 10 % OADC) were treated with or without clofazimine at MIC 60x, 100x and 300x for 8 days. For all studies, samples were taken at indicated time points, serially diluted in PBS containing 0.01 % tyloxapol and plated onto 7H11 OADC agar plates. Plates were incubated at 37 °C for 4 weeks to determine CFU counts.

ROI assay

ROI production in *Mtb* strains ($OD_{600} \sim 1.0$) was measured using the dihydroethidium ROI sensing dye (DHE, excitation/emission at 500/605 nm). *Mtb* strains were cultured in Middlebrook 7H9 media supplemented with 0.2 % glycerol and 0.01 % tyloxapol at 37 °C with either 10 % OAD (oleic acid, albumin, dextrose) with/without 0.25 mM cumene hydroperoxide (CHP) or 10 % OADC (oleic acid, albumin, dextrose, and catalase) with or without 60x MIC of CFZ for 16 h in 4 replicates. After treatment, *Mtb* cultures were washed by centrifugation (3000 x g) and resuspended in 1x PBS (pH 7.4) containing 10 μ M DHE, incubated further for 20 min at 37 °C followed by two washes with PBS to remove residual extracellular dye. The fluorescence of DHE-stained cells was acquired with a FACS Aria III cell sorter using the 500 nm laser excitation, and BP 610/20 nm for emission acquisition (PerCP-Cys5.5). The cells were acquired at a constant flow rate of setting 4 and a threshold rate of approximately 1,000-2,000 events per second and 100,000 total events were recorded per sample. For analysis, the bacterial population was identified according to the forward and side scattering property of the population (FSC versus SSC). To obtain single cell populations, bacterial aggregation was removed from the data analysis using doublet discrimination from the FCS-height vs FCS-area plots. The percentage of DHE+ cells and mean fluorescent intensity were calculated with FlowJoTM v10.4.2 (Tree Star, Ashland, OR).

Identification of proteins by LC-MS/MS

The entire Bi_2S_3 stained protein band was excised from the gel, rinsed with water, and cut into approximately 1 mm x 4mm pieces using a sterile scalpel. The gel slices were then rinsed with 100 mM ammonium bicarbonate solution and collectively transferred into a sterile Eppendorf® LoBind 1.5 ml microcentrifuge tube. 500 μ l of acetonitrile (ACN) was added and the sample was incubated on ice for 10 min. The sample was then briefly centrifuged, the acetonitrile removed and 100 μ l of 10 mM dithiothreitol (DTT) solution was added to rehydrate the gel pieces and reduce the proteins. The sample was incubated in 10 mM DTT solution at 56 °C for 30 min, removed, cooled to room temperature and then 500 μ l of ACN was added and the sample was incubated on ice for 10 min. The sample was then centrifuged and the supernatant removed, then 100 μ l of 55 mM iodoacetamide solution was added and the sample was incubated at room temperature for 30 min in the dark to facilitate protein alkylation. Following alkylation, 500 μ l of ACN was added and the sample was incubated on ice for 10 min. All solution was then removed and 200 μ l of trypsin (Promega, sequence grade) solution at a concentration of 13 ng/ml was added to the gel slices, the sample was mixed gently and incubated at 4 °C for 2 h to allow the gel slices to re-hydrate and slow diffusion of trypsin into the polyacrylamide gel matrix. The samples were incubated in the trypsin solution at 37 °C, overnight (18-24 h) for optimum in-gel protein digestion. The resulting peptides were extracted by adding 400 μ l of 5% formic acid/acetonitrile (1:2, v/v)

solution to the sample followed by 15 min incubation at 37 °C on a shaking heating block set at 450 rpm. The sample was briefly centrifuged, the solution transferred to a sterile Eppendorf® LoBind microcentrifuge tube, and the sample dried using a SpeedVac concentrator (Labconco, USA) set at 40 °C. The dried, extracted peptides were then reconstituted in 50 µl of 5% formic acid solution, transferred to a glass vial and 1 µl of sample was injected for nano-LC-MS/MS analysis.

The peptide digests were analyzed using a Thermo Q Exactive Orbitrap mass spectrometer coupled to a Dionex UltiMate 3000 UPLC system. The tryptic peptides were maintained at 6 °C in the autosampler and were separated on a 15 cm nano capillary column (ID 75 µm) packed in the laboratory with Supelco 3.5 µm C18 stationary phase. A 45 min gradient from 1% acetonitrile, 99% water/0.1% formic acid, to 50% acetonitrile/water, 0.1% formic acid, flow rate 300 nl/min, was used for the analysis. Peptide fragment mass spectra were acquired using a full MS, data dependent MS2 Top 10 method. The MS RAW files were processed using Thermo Scientific™ Proteome Discoverer™ 2.2 software and SEQUEST™ peak-finding search engine application to compare the mass spectra to the *Mtb* FASTA database to identify relevant proteins and peptides. The method was set to consider carbamidomethyl modifications and methionine oxidation. The protein candidates were then screened for pyridoxal phosphate binding domains and potential roles in sulfur metabolism. A targeted method was constructed using the 5 strongest peptide fragment ions for the most likely candidate, Rv3684/Cds1, and the samples re-analyzed using this method to confirm the presence of this protein.

Preparation of mycobacterial genomic DNA

Genomic DNA was isolated from *Mtb* H37Rv as follows: *Mtb* H37Rv was grown to late log phase (OD₆₀₀ = 1.0) in 50 ml 7H9 liquid media. Cells were harvested (2,000 x g, 20 min) supernatant was discarded and 6 ml of a freshly prepared solution of 3 parts chloroform to 1-part methanol added. Tubes were then vortexed for 1 min. Tris-buffered phenol (6 ml) was then added and the tube vortexed for a further 30 sec. Finally, 9 ml of 4 mM guanidine thiocyanate solution were added, and the tubes inverted several times. After centrifuging at 2000 x g for 15 min the upper phase was removed, and an equal volume of isopropanol added to precipitate genomic DNA. The DNA was collected by centrifugation and washed with 70% ethanol before being air dried and suspended in 100 µl Tris-EDTA, pH 7.5.

Construction of $\Delta cds1$ and $\Delta rv1077$ mycobacterial strains

The *rv1077* (*cbs*) and *rv3684* (*cds1*) knockout *Mtb* strains were generated by homologous recombination using specialized phage transduction according to Badarov *et al.* (2002)³⁶. The *cds1* allelic exchange substrate (AES) phasmid was a kind gift from Michelle Larsson

(Albert Einstein College of Medicine). The AES contains *cds1* disrupted by the hygromycin resistance gene. Briefly, the AES phasmid was amplified in *E. coli* DH5 α and purified using a DNA plasmid Mini-prep kit (Thermo). *M. smegmatis* was then transduced with the AES and a high titer phage lysate prepared. *Mtb* H37Rv was grown to an OD₆₀₀ of ~0.8 and washed twice with buffer (50 mM Tris-HCl, pH 7.6, 150 mM NaCl, 10 mM MgCl₂, 2 mM CaCl₂) then mixed with the high titer phage lysate in a 1:1 (CFU:plaque forming units) ratio and incubated at 37 °C overnight. After centrifugation (16,000 x g, 10 mins, 4 °C) the pellet was resuspended in 0.2 ml 7H9 media and plated on hygromycin selective 7H10 agar. After 3 weeks at 37 °C, 5 individual colonies were inoculated in 7H9 media supplemented with 50 μ g/ml hygromycin. Genomic DNA of each colony was extracted, and gene deletion confirmed using PCR with primers Rv3684CF, Rv3684CR (*rv3684*) or Rv1077CF, Rv1077CR (*rv1077*) and UUT (See Supplementary Table 4).

Mycobacterial complementation

The *cds1* ORF was PCR amplified from genomic *Mtb* DNA using KOD Xtreme HotStart DNA polymerase (Roche) according to the manufacturer's protocol and primers (Rv3684F and Rv3684R). The PCR product and pMV261 vector were digested with *Bam* HI and *Cla* I (Thermo), isolated using agarose purification, and ligated using T4 DNA ligase (NEB) to produce pMV261::*hsp₆₀-cds1*. A second complementation vector was constructed. The ORF of *rv3682*, *rv3683* and *cds1*, with an additional 500 bp upstream region, was PCR amplified using primers ponABCF and ponABCR. The amplicon was digested using *Bam* HI and *Cla* I and ligated into the pMV261 vector. Complementation vectors expressing *cds1* under the control of either the *hsp₆₀* or native promoter were electroporated (Gene Pulser Xcell, Biorad) into the *Mtb* Δ *cds1* strain and transformants selected on 7H10 agar plates containing hygromycin (50 μ g/ml) and kanamycin (25 μ g/ml). The vectors were similarly electroporated into *M. smegmatis*. Complemented strains were grown in 7H9 media containing 25 μ g/ml kanamycin.

Purification of recombinant proteins

The *cds1* 1041 bp open reading frame was PCR amplified using *Mtb* genomic DNA and primers Rv3684CEF and Rv3684CER (see Supplementary Table 4). The PCR product was digested with *Nde* I and *Bam* HI and then ligated into the pET15b expression vector previously digested with *Nde* I and *Bam* HI. These restriction sites are in the pET15b MCS downstream of a 6-His coding region, resulting in addition of a 6-His tag to the N-terminus of the encoded protein. The ligated construct (pET15b-*cds1*) was then verified by sequencing. *E. coli* BL21 (DE3) cells were transformed with pET15b-*cds1* and grown until the OD₆₀₀ reached 0.5-0.6. Protein expression was induced by the addition of 0.4 mM of IPTG

followed by growth overnight at 18 °C. The cells were pelleted by centrifugation at 5000 rpm for 10 mins, sonicated, and the lysate used for protein purification using nickel-affinity resin (Bio-Rad) by gravity chromatography. pET28b-EhOASS expressing recombinant OASS containing an N-terminal 6xHis tag was overexpressed and purified from *E. coli* as described previously⁴⁵.

Cds1 enzyme kinetics

The rate of H₂S production by purified recombinant Cds1 was monitored via formation of Bi₂S₃, which has an absorbance maximum at 405 nm³¹. Briefly, purified Cds1 enzyme (1 µg of enzyme in 20 µl buffer) and 180 µl of BC solution were mixed in a well of a flat bottom clear 96-well plate (Costar). Bi₂S₃ formation was monitored at room temperature over 30 mins (readings taken once per minute) using a Biotek Synergy H1 hybrid plate reader. The absorbance at 405 nm was converted into product concentrations using the Beer-Lambert equation. The molar absorption coefficient for Bi₂S₃ was determined to be 3,156.9 M⁻¹cm⁻¹ using Na₂S·9H₂O (Sigma) as a standard. Initial velocities were calculated and plotted against Cys concentrations. The K_m and V_{max} values were determined in GraphPad Prism (version 8.4.3) using the Michaelis-Menten equation. The k_{cat} values were calculated by dividing V_{max} by the nanomoles of enzyme used in the reaction.

Identification of Cds1 enzymatic products by LC-MS/MS

Purified Cds1 was added to three separate reaction tubes containing 50 µl of 20 mM Cys in PBS (20 mM Na₂HPO₄, 100 mM NaCl, pH 7.5, 20 µM PLP) and the reaction was allowed to proceed for 15 minutes at room temperature. The reactions were stopped by heating to 80 °C for 5 minutes and the tubes centrifuged at 15,000 rpm for 5 mins. 10 µl aliquots of each reaction solution were taken from the supernatant and analysed by LC-MS/MS. We then identified the enzymatic products of Cds1 using ultra high liquid chromatography coupled to high resolution/high accuracy mass spectrometry based on the analyte's exact mass and HPLC retention time compared to authentic metabolite reference standards. A reference standard mixture of important negatively charged metabolites, including pyruvate and the study samples were analysed on the Q Exactive LCMS system, as described elsewhere, using high resolution molecular ion scans. The RAW files were subjected to post-run analysis using Skyline software along with a template constructed to monitor the relevant analytes. The exact theoretical mass for ¹²C pyruvate standard, is 87.008768 (87.0088) Da. The standard was present in the molecular ion scans with the same exact mass, in the standard mixture when subjected to analysis. The retention time for the pyruvate in standard mix on the Aminex column used is 11.0 min. In the samples, a peak was observed with the

same retention time and exact mass as pyruvate standard and this was considered sufficient evidence for verification of identity. Each sample was assayed in triplicate.

***In vitro* CFU assay.** Thioglycollate-elicited peritoneal macrophages were isolated from C57BL/6 mice²³ and were plated at 1.0×10^6 cells per well in 6-well plates. Cells were infected with *Mtb* strains at an MOI of 0.2 and incubated at 37 °C for 2 hours, followed by washing cells twice to remove non-internalized bacilli (day 0 post infection). At 0, 1, 2 and 4 days, cells were lysed with DPBS containing 0.05% SDS and CFUs were determined by plating serial dilutions of lysates on 7H11 agar plates supplemented with 10% OADC. Plates were incubated at 37 °C with 5% CO₂ for 4 weeks to determine CFU counts.

LC-MS/MS targeted metabolomics analyses

Mtb strains in replicate were inoculated from freshly grown culture in 7H9 media (containing 0.01% Tyloxapol, 0.2% glycerol, 10% OADC) with 4 mM Cysteine at an OD₆₀₀ of about 0.05. These strains were cultured (~30 ml each) in inkwell bottles to an OD₆₀₀ of ~0.8 at 37 °C with shaking (150 rpm). Each culture was pelleted by centrifuging at 3,500 x g for 10 min. The culture supernatant was discarded, and cells were washed three times with 7H9 containing 0.01% Tyloxapol. After the last wash, the pelleted cells were resuspended in 5 ml of 7H9 media containing 0.01% Tyloxapol, 0.2% glycerol, 10% OAS (oleic acid, bovine albumin and NaCl), 0.2% [U-¹³C]-Glucose (Sigma-Aldrich) or 0.01% Tyloxapol, 0.2% glycerol, 10% OADS (oleic acid, bovine albumin, dextrose and NaCl), 100 µM [U-¹³C]-Cysteine (Cambridge Isotope Laboratories Inc.), or 7H9 media containing 0.01% Tyloxapol, 0.2% glycerol, 10% OAD, 0.25 mM CHP. After resuspension of the pellet, the cultures were then incubated overnight at 37 °C with shaking (150 rpm) and harvested by centrifugation at 3,500 x g for 3 min. Cells pellets were immediately snap frozen on dry ice for about 5 mins and then thawed and prepared for lysis using a Magnalyser (Roche) at 7000 rpm for 1 minute followed by cooling on ice for 4 min, repeated 3-4 times. The lysis was performed using a 1.8 ml solution of methanol, acetonitrile, and water in the ratio of 2:2:1). The lysate was then centrifuged at 15,000-17,000 x g for 10 min. The supernatant was collected and filtered through a 0.22 µm filter. The recovered lysate was then vacuum concentrated to dryness (Eppendorf Concentrator Plus) at 30°C for 12 h. The dried lysate pellets were then resuspended in 200 µl of purified water. 100 µl of this suspension for each replicate was submitted for LC-MS/MS targeted organic acid (metabolites) analysis and 100 µl (50 µl resuspension plus 50 µl acetonitrile) was submitted for LC-MS/MS targeted amino acid analysis.

LC-MS/MS was used for relative quantification of each organic acid and amino acid. The LC-MS/MS sample analysis was performed using a Thermo Scientific Dionex Ultimate

3000 UHPLC system coupled to a Thermo Scientific Q-Exactive Mass Spectrometer with a HESI source. A sample volume of 1 μ l was injected onto a Waters Xbridge® BEH HILIC HPLC column (2.5 μ m particles, 2.1 x 100 mm), column oven set at 40 °C and chromatographic separation was performed using gradient elution at a flow rate of 200 μ l/min and total run time of 26 min. Mobile phase A contained water with 0.1 % formic acid and mobile phase B contained acetonitrile with 0.1% formic acid. Data was acquired using full scan MS (without HCD fragmentation) in positive mode, over the m/z range 50 – 750 Da at 70000 resolution. A QC sample was prepared using 21 different amino acids at a concentration of 500 ng/ml to monitor amino acid retention time consistency and MS sensitivity. Each sample was spiked with deuterated Alanine (D4-Alanine) as an internal standard to monitor processing efficiency and data normalization. The data was processed, and peak areas were calculated using Skyline 3.7 (MacCoss Lab, University of Washington, Seattle, WA, USA).

Total ATP quantitation

ATP quantitation was performed on cell lysates prepared for use in our metabolomics analysis (see **LC-MS/MS targeted metabolomics analysis** for bacterial growth conditions and sample preparation). ATP levels of cell lysates were measured using a Roche ATP Bioluminescence kit CLS II according to the manufacturer's instructions. ATP levels were normalized to the protein concentration of each cell lysate.

Statistics

Unless specified in the materials and methods, all experiments were performed on 3 to 8 biological replicates and the data were expressed as mean $\pm$ SD or mean $\pm$ SEM. Statistical significance of the data was determined using GraphPad Prism software (Version 8.0), (GraphPad Software, Inc.). Specific statistical tests are noted in the figure legends and include the Student's unpaired t-test (two-tailed), and one-way or two-way ANOVA.

Data availability

Proteomics data has been deposited to the ProteomeXchange Consortium via the PRIDE partner repository with the dataset identifier PXD022969. The source data underlying the main Figures and the Supplementary Figures 1-15 are provided as a Source Data file.

Acknowledgements

This work was supported by NIH grants R01AI134810, R01AI137043, R33AI138280, a Bill and Melinda Gates Foundation Award (OPP1130017), South Africa (SA) MRC, SA NRF BRICS Program to AJCS, and CSIR to TTRK. We thank Drs. Michelle Larson (Albert Einstein College of Medicine, NY) for providing the specialized transducing phage for *rv3684* and Alessandro Giuffrè (CNR Institute of Molecular Biology and Pathology, Rome, Italy) for providing the OASS expressing plasmid.

Author contributions

A.J.C.S., T.T.R.K., M.A.R. designed the research.
T.T.R.K., M.A.R., J.N.G and A.J.C.S wrote the paper.
T.T.R.K., M.A.R., B.E.T., J.S.M. and R.R.S. performed research.
J.H.A performed LC-MS/MS analyses.
T.T.R.K., M.A.R., V.S., D.A.L., J.R.L. and M.B. analyzed data.

Figure Legends

Figure 1. Mycobacterial species produce H₂S. (a) Detection of H₂S in the headspace of cultures of mycobacterial species using lead acetate strips. *Msm*; *M. smegmatis*, BCG; *M. bovis* BCG, *Mbo*; *M. bovis*, *Mtb*; *Mtb* H37Rv, CDC; *Mtb* CDC1551, MDR; multi-drug resistant and DS; drug-sensitive clinical strains of *Mtb*. Note: Strips shown, (Figure 1a top insert) were scanned after 48 h of incubation. The inkwell bottles shown are representative of an independent experiment after 72 h of incubation. (b) Estimation of H₂S production by quantifying lead sulfide staining (Figure 1A top insert) using densitometric analysis. Data normalized to the optical density (OD₆₀₀) of each culture; *n* = 3. (c) Microplate-based BC assay showing H₂S production by live and heat-killed *Mtb* H37Rv. Time course measurement of H₂S production using BC assay for (d) intact *Mtb* H37Rv cells, (*n* = 5 – 8) and (e) lysates with different concentrations of Cys, (*n* = 3 – 4). BC assay of (f) intact *Mtb* H37Rv cells, (*n* = 3 – 5) and (g) *Mtb* H37Rv lysates in the presence of AOAA showing reduced H₂S production, (*n* = 4). No significant inhibition of H₂S production for (h) intact *Mtb* H37Rv cells, (*n* = 3 – 4) and (i) lysates was demonstrated in the presence of PAG, (*n* = 4). A Unisense A/S H₂S microsensor was used to measure the H₂S concentration in (j) *Mtb* H37Rv cultures and bacteria-free supernatants, (*n* = 4). Microsensor measurements of real-time H₂S production in *Mtb* H37Rv lysates in assay buffer (0.4 M triethanolamine-HCl, pH 8.0; 20 μM PLP, 10 mM EDTA) with (k) 20 mM Cys, (l) stepwise addition of Cys (arrows indicate the amount of Cys (mM) added at the time point) and (m) 20 mM Cys followed by the addition of *Mtb* lysate preincubated with AOAA (4 mM). Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean ± SD from the indicated *n* (number of replicates per data set) except for (K, L and M), which show representative real-time measurement for one sample with 2-3 independent repeats. All *P* values are relative to untreated controls or as indicated. Statistical analysis was performed using GraphPad Prism 7.02. One-way ANOVA with Dunnett's multiple comparisons test was used to determine statistical significance. **P* < 0.05, ***P* < 0.01, ****P* < 0.001, #*P* < 0.0001.

Figure 2. Identification of H₂S-producing enzymes in *Mtb*.

(a) Equal quantities of mycobacterial lysates were resolved on a native polyacrylamide gel (PAGE) and assayed for H₂S production by in-gel BC assay. The arrow indicates the predominant H₂S producing enzyme, upper band, for most of the mycobacterial species except for *Msm*. (b) The effect of PLP and AOAA on the production of H₂S in *Mtb* H37Rv lysate using an in-gel BC assay. All lanes were loaded with equal amounts of lysate (*n* = 2 – 3). (c) Identification of Rv3684 from *Mtb* lysate resolved native-PAGE. Trypsin digested

peptide fragments of Rv3684 identified using LC-MS/MS. The observed peptide fragments distribution (blue and pink shade over the full-length peptide map) and their amino acid sequence are shown. PSM - peptide spectrum matches; MH⁺ (Da) - protonated, monoisotopic mass of the peptide. Retention time of each LC-MS/MS identified peptide of Rv3684 are shown (right panel, Fig. 2C). **(d)** Schematic showing H₂S-generating enzymes and their reactions in the reverse transsulfuration pathway. **(e)** SDS-PAGE analysis of eluted fractions of purified His-tagged Rv3684 expressed in *E. coli*. **(f)** LC-MS/MS identification and quantification of pyruvate from Rv3684 using Cys (10 mM) as a substrate, (*n* = 3). **(g)** Michaelis-Menten plot of initial reaction velocity as a function of Cys concentration used to determine the *K_m* and *k_{cat}* of purified Rv3684. H₂S-producing activity of purified Cds1 (Rv3684) using BC assay and inhibition with AOAA, (*n* = 4). **(h)** Proposed catalytic activity of Cds1 using Cys as a substrate. Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean ± SD from the indicated *n* (number of replicates per data set).

Figure 3. Deletion of *rv3684* in *Mtb* reduces H₂S production. **(a)** The proposed operonic location of *rv3684*. Bacterial lysates resolved in native PAGE were assayed for H₂S production using in-gel BC assay in **(b)** *Mtb* CDC1551, CDC *Tn::rv3682* and CDC *Tn::rv3683*; (*n* = 3) and **(c)** *Mtb* H37Rv, *Δcds1* and *comp* (*n* = 2). The arrow indicates the Cds1 band. H₂S production in intact *Mtb* H37Rv, *Δcds1* and *comp* cells, (*n* = 8) **(d)**, and lysates (*n* = 3 - 4) **(e)**, using the BC method (in the presence of 20 μM PLP and 20 mM Cys). **(f)** Growth (OD₆₀₀) of *Mtb* H37Rv, *Δcds1* and *comp* cultures after 8 days in 0, and 4 mM Cys, (*n* = 3 - 4). **(g)** Phylogenetic tree of Cds1 (Rv3684) homologs in different *Mycobacterium* sp. and other bacteria (NCBI protein accession number) and > 65% amino-acid identity with Cds1. **(h)** putative sulfur metabolism proteins in *Mtb* H37Rv (NCBI protein accession number and their % identity with Cds1 provided). Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean ±SD or ±SEM (panel **e**) from the indicated *n* (number of replicates per data set). Statistical analysis was performed using GraphPad Prism 7.02. One-way ANOVA with Dunnett's multiple comparisons test was used to determine statistical significance. #*P* < 0.0001.

Figure 4. Conferring H₂S producing activity in *M. smegmatis*. **(a)** Equal quantities of bacterial lysates from *Mtb* H37Rv, *Msm*, and *cds1*-expressing *Msm-wt_p-cds1* and *Msm-hsp₆₀-cds1* cells were resolved on native PAGE and assayed for H₂S production using in-gel BC assay, (*n* = 2). **(b)** BC assay of H₂S production in *Msm* lysates. pMV261 - *Msm* transformed with an empty pMV261 vector (*Msm*-pMV261), and buffer - lysate suspension buffer and BC solution, (*n* = 4). **(c)** Time course of H₂S production in intact *Msm* cells in the

presence of 0 and 10 mM Cys, ($n = 4$) **(d)** H_2S production in intact *Msm* cells in the presence of 0, 1, 10 and 20 mM Cys after 140 mins, ($n = 4$). **(e)** Growth kinetics (OD_{600}) of *Msm* strains in Cys-containing media, ($n = 3$). **(f)** Relative percent growth of *Msm* strains in Cys-containing media after 48 h, ($n = 3$). Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean $\pm$ SD or $\pm$ SEM (panel **c** & **e**) from the indicated n (number of replicates per data set). Statistical analysis was performed using GraphPad Prism 7.02. One-way ANOVA (panel **b**) and two-way ANOVA (panel **d** & **f**) with Dunnett's multiple comparisons test were used to determine statistical significance. *** $P < 0.001$, # $P < 0.0001$.

Figure 5. Endogenous H_2S stimulates respiration in *Mtb*. *Mtb* respiration was measured using an Agilent Seahorse XF96 Analyzer. **(a)** An OCR profile showing the basal respiration of *Mtb* strains, ($n = 5 - 7$) **(b)** %OCR of *Mtb* upon addition of Cys, ($n = 3 - 5$) **(c)** Fold OCR of *Mtb* strains relative to media control in the presence of 4 mM Cys, ($n = 3 - 7$) **(d)** %OCR of *Mtb* with sequential injection of Cys and AOAA (1mM), or media (Med) as a control, ($n = 3$) and **(e)** Measurement of H_2S concentration in an OASS enzymatic activity assay using the Unisense H_2S microsensor. H_2S levels rapidly diminished after addition of OASS and substrate O-acetyl-L-serine (OAS) **(f)** %OCR of *Mtb* after injecting either Cys or OAS or Cys, OAS and OASS, ($n = 3 - 4$). **(g)** %OCR of *Mtb* after injecting either Cys or Cys and OAS, ($n = 3 - 4$). **(h)** Model showing how H_2S stimulates respiration via both oxidases (dotted line arrows) and how respiration was reduced by exogenous addition of the H_2S consuming enzyme OASS, and endogenous CysK1. Red "X"; inhibition, blue arrow; increased OCR. **(i)** Model showing electron flow through Complex I to the menaquinone pool (MK) and then through Complex III/IV (cytochrome bc_1/aa_3), or re-routing of electrons through cytochrome bd if Complex III/IV is inhibited by Q203. This contributes to the proton-motive force, which powers ATP synthesis by Complex V (ATP synthase). OCR profiles of WT *Mtb* **(j, l)** or $\Delta cydAB$ cells **(k, m)** exposed to Cys, or Cys and Q203 (300x MIC_{50}), ($n = 3$). Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean $\pm$ SEM or $\pm$ SD (panel **a**) from the indicated n (number of replicates per data set). Statistical analysis was performed using GraphPad Prism 7.02. One-way ANOVA with Dunnett's multiple comparisons test (unpaired t-test for panel **d**) was used to determine statistical significance. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, # $P < 0.0001$.

Figure 6. Cds1 regulates sulfur metabolism in *Mtb*. Schematic (middle) showing metabolites in the transsulfuration pathway (black) linked with the glycolysis and TCA cycle (blue). LC-MS/MS analysis of metabolites in *Mtb* strains cultured in 7H9 medium with [U- ^{13}C]-Cys (100 μ M) **(a-g)** or [U- ^{13}C]-glucose (0.2%) **(h-m)**. Representative experiments are

shown in each panel, each experiment was repeated at least twice. Data shown represent the mean $\pm$ SEM for $n = 3 - 5$ biological replicates. Statistical analysis was performed using GraphPad Prism 7.02. Two-way ANOVA with Dunnett's multiple comparisons test was used to determine statistical significance. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$, $****P < 0.0001$.

Figure 7. Cds1 regulates central metabolism in *Mtb*. Cds1 in *Mtb* regulates amino acids (turquoise), Cys (red), and glycolysis and the TCA cycle metabolites (blue). LC-MS/MS analysis of (a) amino acids, and (b) glycolysis, pentose phosphate pathway and TCA cycle metabolites indicated by heat maps (top) and total abundance. *Mtb* strains were cultured in 7H9 medium with [U-¹³C]-Cys (100 μ M). (c) ATP levels measured in *Mtb* strains with (+) and without (-) 100 mM Cys. Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean $\pm$ SEM for $n = 3 - 5$ biological replicates. Statistical analysis was performed using GraphPad Prism 7.02. Two-way ANOVA (panel a & b) or one-way ANOVA (panel c) with Dunnett's multiple comparisons test were used to determine statistical significance. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$, $****P < 0.0001$.

Figure 8. Endogenous H₂S in *Mtb* exacerbates the effect of oxidative stress and increases susceptibility to CFZ. (a) Intracellular ROI levels shown as the percent of DHE-positive *Mtb* cultured in 7H9 media supplemented with or without catalase, ($n = 4 - 5$). (b) LC-MS/MS analysis showing total abundance and carbon isotopologue distribution of EGT and MSH in *Mtb* strains cultured in [U-¹³C]-glucose, ($n = 3 - 5$). (c) Intracellular ROI levels after exposure to 0.25 mM cumene hydroperoxide (CHP) for 16 h, ($n = 4$). (d) Survival of bacilli after exposure to 0.25 mM CHP for 16 h, ($n = 3$). Bacilli were treated with clofazimine (CFZ) at 60x MIC and observed for (e) ROI levels after 24 h of treatment, ($n = 5$) and (f) survival after 8 days of treatment, ($n = 3$). CFU of *Mtb* after exposure to different amount of NaHS with or without 60x MIC of CFZ for 5 days (g) or 11 days (h), ($n = 3$). (i) Survival of *Mtb* after exposure to different amounts of NaHS with or without RIF (60x MIC) or INH (60x MIC) for 5 days, ($n = 3$). (j) Schematic diagram showing endogenous H₂S production in *Mtb* leading to increased respiration (OXPHOS) and suppression of glycolysis. Also indicated is recycling of H₂S to generate Cys, which regulates redox balance via MSH and EGT. Red arrows showing up; increase, down; decrease. Thick/thin blue arrows, more/less pronounced effects, respectively. Representative experiments are shown in each panel, each experiment was repeated at least twice. Data shown represent the mean $\pm$ SD (or mean $\pm$ SEM for panel b) from the indicated n (number of biological replicates). Data were analyzed using Excel 2017 and statistical analysis and data presentation performed using GraphPad Prism 7.02. One-way ANOVA with Tukey's (panel a, e, and i) or Dunnett's (panel

1438 **c, g, and h**) multiple comparisons test were used to determine statistical significance. Two-
 1439 way ANOVA with Tukey's multiple comparisons test was used to determine statistical
 1440 significance for (**b, d** and **f**). * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, # $P < 0.0001$, nd = not
 1441 detected.
