Running head: Ecological drivers of Hendra virus shedding

Keywords: bats; nutritional stress; pathogen spillover; generalized additive models
Abstract

The ecological conditions experienced by wildlife reservoir hosts affect the amount of pathogen they excrete into the environment. This then shapes pathogen pressure, the amount of pathogen available to recipient hosts over space and time, which affects spillover risk. Few systems have data on both long-term ecological conditions and pathogen pressure, yet such data are critical for advancing our mechanistic understanding of ecological drivers of spillover risk. To identify these ecological drivers, we here reanalyze shedding data from a spatially replicated, multi-year study of Hendra virus excretion from Australian flying foxes in light of 25 years of long-term data on changing ecology of the bat reservoir hosts. Using generalized additive mixed models, we show that winter virus shedding pulses, previously considered idiosyncratic, are most pronounced after recent food shortages and in bat populations that have been displaced to novel habitats. We next derive the area under each annual shedding curve (representing cumulative virus excretion) and show that pathogen pressure is also affected by the ecological conditions experienced by bat populations. Finally, we illustrate that pathogen pressure positively predicts observed spillover frequency. Our study suggests that recent ecological conditions of flying fox hosts are shifting the timing, magnitude, and cumulative intensity of Hendra virus shedding in ways that shape the landscape of spillover risk. This work provides a mechanistic approach to understanding and estimating risk of spillover from reservoir hosts in complex ecological systems and emphasizes the importance of host ecological context in identifying the determinants of pathogen shedding.
Introduction

Cross-species transmission can be conceptualized as a series of hierarchical barriers that must be overcome for a pathogen to move from a reservoir host to recipient hosts such as humans [1]. At the beginning of this cascade, the ecological conditions experienced by reservoir hosts shape susceptibility to infection and the likelihood of pathogen shedding (i.e., excretion) [2,3]. For example, droughts have been associated with increased nematode shedding in ungulates [4], and Salmonella shedding by ibis is more likely in urban than rural habitats [5]. This in turn determines pathogen pressure, or the amount of pathogen available to recipient hosts over space and time, which affects the force of infection and the ultimate probability of spillover [6].

Identifying the ecological conditions that drive pathogen pressure could accordingly improve reservoir host surveillance efforts and help predict where and when spillover is most likely [7,8].

Multiple challenges restrict our ability to establish the ecological drivers of pathogen pressure. On the one hand, many host populations must be repeatedly sampled to capture spatial and temporal variation in shedding [9]. This presents logistical difficulties and often necessitates optimized allocation of sampling effort [10,11]. On the other hand, the complex ecological dynamics used as predictors are best characterized with long-term research [12,13]. For example, more than two decades of annual monitoring were necessary to identify the ecological conditions that predict the density of infected nymphal ticks and human Lyme disease risk [14]. As such, the general sparsity of long-term, ecological data in many wildlife pathogen systems limits inference about the possible factors that shape pathogen pressure from reservoir hosts. Systems with data on pathogen pressure and long-term ecological conditions are critical for advancing our mechanistic understanding of spillover and to identify likely drivers in less studied systems.
Hendra virus (HeV) shedding from Australian flying foxes (Pteropus spp.) provides an ideal system to identify the ecological conditions that predict pathogen pressure [15]. HeV emerged in 1994, causing an outbreak of a lethal disease in horses and then humans that has been followed by over 60 spillovers through 2019 across eastern Australia [16,17]. Flying foxes are the natural reservoirs of HeV [18], and transmission to horses likely occurs via contact with pasture, feed, or water contaminated with urine, saliva, or feces [19]. Spatiotemporal sampling of bat roosts has revealed shedding pulses during the Austral winter in subtropical regions, yet their occurrence varies both spatially and interannually [20]. This suggests that seasonal processes such as births and climate shifts cannot solely drive pathogen pressure [21]. The mechanisms underlying shedding pulses remain poorly understood but have been hypothesized to stem from synchronous ecological conditions that affect bat behavior and within-host processes [22–25].

Traditionally, flying foxes move nomadically to find ephemeral sources of nectar in native forests [26,27]. However, few dietary plants reliably flower in the Austral winter [27,28]. These plants occur in forests that have been mostly cleared for agriculture and urbanization, making native winter feeding habitat scarcer and more dispersed [29]. Eucalypt flowering is especially vulnerable to disruption from temperature and rainfall variability [28,30], and occasionally winter or spring nectar fails, leading to acute food shortages and periods of nutritional stress [27,31,32]. Bats have responded to these changes by splitting into smaller roosts that are closer to reliable, often introduced, food in agricultural areas and urban gardens [27,33]. Bats in these newly established and continually occupied roosts supplement their diet with non-native plants [34,35]. This change in behavior has expanded the winter distribution of flying foxes in subtropical Australia into areas that do not provide native winter food [36,37].
Reliance on agricultural and urban dietary resources when native plants are unavailable could combine with other energetic stressors, such as seasonal reproduction and the more extreme temperatures that bats can experience in these newly established roosts outside their historic wintering range [38–40]. These stressors could alter bat within-host dynamics (e.g., immunosuppression) in ways that increase susceptibility to HeV or facilitate reactivation from chronic infections [22,24,25,41]. Periods of nutritional stress have been associated with poor body condition and elevated HeV seroprevalence in little red flying foxes (P. scapulatus) [31]; moreover, poor condition was a correlate of HeV infection in black flying foxes (P. alecto) but was negatively correlated with HeV seroprevalence in P. alecto and grey-headed flying foxes (P. poliocephalus) [42,43]. The relationships between food shortages and HeV shedding therefore remain poorly understood, especially in the context of the changing ecological conditions experienced by these bat hosts. Recent work suggests such ecological changes have increased the frequency of HeV spillovers (Eby et al., in review) [17,44], but the mechanisms linking food shortages and dramatic shifts in bat behavior with virus shedding dynamics remain unresolved.

Here, we reanalyze shedding data from a spatially replicated, multi-year study of HeV in flying foxes in light of long-term data on bat ecology to test whether food shortages and recent shifts in flying fox behavior amplify pathogen pressure. We first ask whether these ecological conditions can explain seemingly idiosyncratic seasonal shedding pulses while also accounting for underlying spatiotemporal variation in infection dynamics and roost composition, including species with high competence (e.g., P. alecto) [45–47]. We next quantify pathogen pressure per year and per roost and test whether bat ecology also predicts cumulative seasonal shedding intensity across the landscape. Finally, we assess the relationship between pathogen pressure and the frequency of realized spillover events. Our work thus provides a mechanistic approach to
understanding bat-borne virus spillover risk as well as a new method for estimating these risks from multiple ecological predictors. Bats throughout the eastern hemisphere are experiencing similar stressors owing to land conversion [23,48], underscoring the general need to better understand the likely consequences for pathogen shedding and subsequent spillover risk.

Materials and methods

Spatiotemporal data on HeV shedding

We reanalyzed a previously published longitudinal dataset of HeV shedding from flying foxes spanning July 2011 to November 2014 across New South Wales and Queensland [20]. Sampling consisted of urine collection from quadrants of 3.6 m x 2.6 m plastic sheets placed under roosts at primarily monthly intervals [49]. Urine was pooled per quadrant and screened by quantitative RT-PCR targeting the HeV M gene to determine presence or absence of viral shedding in a roost [50]. We aggregated data to the scale of week and determined HeV prevalence as the proportion of positive urine pools. Similarly, we calculated the median number of all flying foxes and for each Australian Pteropus species per roost per time interval. We restricted HeV data to an area of subtropical eastern Australia (i.e., mid-to-northeast New South Wales, southeast Queensland) that represents our study region for long-term data on bat ecology (see below) and includes the locations of almost all subtropical HeV spillovers [15]. We further restricted analyses to 2012 through 2014, as 2011 sampling mostly occurred at a single roost [20]. We also limited analyses to roosts sampled in at least two of the three years and in at least three timepoints per year. We thus analyzed prevalence data from nine roosts sampled in 2012–2014 (n=196 weeks; Fig. 1).

Roost-level ecological conditions
We paired HeV prevalence data within our study region with long-term data on flying fox behavior. As described in full in Eby et al. (in review), we used data held by Australian state governments, flying fox surveys conducted between 1998–2005 and 2012–2019, records held by local land managers and experienced observers, and direct observation by the authors to characterize the ecological conditions experienced by bat populations over time [27,28,37].

Roosts were classified as belonging to their historic winter range (and thus where bats rely on native winter dietary plants) or to newly established overwintering regions (and thus where native food is unavailable). We also used these data to identify regional food shortages, acute periods associated with reduced flowering of native dietary plants or no flowering (Table 1).

Analyses of HeV shedding

To test if roost type (i.e., historic or new overwintering regions) and regional food shortages affect seasonal HeV shedding, we fit generalized additive mixed models (GAMMs) with a binomial response to urine pool prevalence with the mgcv package in R [51,52]. GAMMs can flexibly approximate the temporal dynamics of infectious diseases, even when underlying transmission mechanisms are unknown [53,54]. Our fixed effects included a cyclic cubic spline for week, ordered factors of roost type and regional food shortage, and all possible interactions. We used regional food shortages from the prior year (i.e., October 2012 and October–November 2013; Fig. 1) owing to previously observed associations between spring and summer food shortages and subsequent winter spillovers of HeV in 2010–2011 and in 2016–2017 [44].

We also adjusted for occupancy of P. alecto using its relative abundance per roost from weekly median flying fox counts. We did not account for co-roosting P. poliocephalus and P. scapulatus, as P. alecto is the only species that has been associated with HeV shedding in our
study region [45,46]. As flying foxes roost in aggregations of up to hundreds of thousands of
individuals, counts and resulting species proportions are estimates. We thus derived a binary
variable denoting if the weekly proportion of *P. alecto* per roost was below or above 25%, the
lowest maximum proportion of this species across all roosts in this dataset (Fig. S1) [20]. This
cutoff accordingly indicates the upper occupancy bound of this species when it is rare. Our
GAMMs also controlled for spatial dependence through a bivariate smooth of longitude and
latitude [55]. To account for residual variation in spatiotemporal shedding, we included a random
factor smooth of week per roost per year [56]. We set the random effect such that all groups can
differ in weekly shedding but are penalized if they deviate too strongly from the global trend.

Given the complexity of our GAMM relative to our sample size, we used an information
theoretic approach to select among competing nested fixed effects. We considered (i) our full
model alongside two simplified GAMMs: (ii) without the three-way interaction between week,
roost type, and prior year food shortage and (iii) without the two-way interaction between the
latter categorical predictors. We fit GAMMs with maximum likelihood (ML) and compared
models using corrected Akaike information criterion (AICc) and Akaike weights (*w*). We
considered models within two ΔAICc to be competitive [57]. We then refit our most supported
models with restricted ML (REML) for parameter estimation and visualizing fitted values.

To quantify cumulative annual shedding intensity, we fit univariate GAMs with binomial
response and cyclic cubic splines for week to our HeV prevalence data per year for each of our
nine roosts (*n*=25; Fig. S2). In rare cases with few (e.g., *n*=3) sampling events and where
prevalence was uniformly zero (i.e., as occurred in two annual time series; Fig S2), we used thin
plate splines to improve convergence. We then calculated the area under each annual shedding
curve (i.e., pathogen pressure; AUC) by integrating the fitted values and confidence intervals
using the Bolstad2 package [53,58]. This measure summarizes the magnitude and duration of
shedding in a single metric, and thus greater pathogen pressure suggests more cumulative HeV-
positive pools per roost per year. We used the metafor package to assess heterogeneity in AUC
through a random-effects model weighted by sampling variance, which we derived from the
number of sampling events per time series [59]. We then used REML to quantify $I^2$, which
measures the contribution of true heterogeneity rather than noise to the variance in AUC [60].

We then assessed the ecological drivers of pathogen pressure using another set of GAMs.
We modeled annual AUC as a Tweedie-distributed response and again weighted these estimates
by the number of sampling events per annual time series. We included roost type and prior food
shortage as categorical predictors alongside a bivariate smooth of longitude and latitude. We also
controlled for the mean annual proportion of $P. alecto$ per roost with a thin plate spline and
assessed sensitivity of our results to two alternative measures of annual relative abundance (e.g.,
median, winter maximum). Lastly, because a small number of our annual time series had short
sampling durations that did not include the Austral winter (Fig. S2), we reran our GAMs after
excluding four annual AUC estimates derived from 20 or fewer weeks of flying fox sampling.

**HeV spillover analyses**
To assess relationships between pathogen pressure and spillover, we collated data on the location
and date of all known HeV cases in horses in our study region between 2012–2014 [15]. As
described in full in Eby et al. (in review), these data were obtained from government notices (i.e.,
New South Wales Department of Primary Industries, Queensland Department of Agriculture and
Fisheries; Business Queensland), ProMED, local media reports, and personal communications.
We aggregated all HeV case locations to the nearest town or regional center for confidentiality.
We derived spatial buffers using the `rgeos` package to collate the total number of HeV spillover events near each of our nine roosts per sampled year. Australian *Pteropus* are highly mobile [32,61], and prior analyses have shown weak spatial synchrony in HeV shedding among flying fox roosts up to approximately 500 km [21]. We therefore used spatial buffers of 50, 100, 200, 300, 400, and 500 km. We modeled counts of spillovers within each buffer through a set of GAMs that used Poisson distributions and penalized splines for pathogen pressure [62]. As in our GAM analyses of AUC, we also included a bivariate smooth of longitude and latitude.

Results

Ecological predictors of seasonal HeV shedding pulses

Our GAMMs revealed that previously observed seasonality in HeV shedding [e.g., 26] is markedly explained by recent changes in bat behavior and by food shortages. The most parsimonious model explained 71% of the deviance and only included interactions between week and both roost type and recent food shortages ($w_i=0.59$; Table S1). Ordered factor smooths indicated that roosts in newly established overwintering regions had distinct seasonal shedding patterns compared to roosts in the historic wintering range ($\chi^2=23.61$, $p<0.001$); roosts that experienced a recent food shortage also displayed distinct shedding seasonality compared to roosts without recent food shortages ($\chi^2=14.33$, $p<0.001$; Table 2). In the absence of recent food scarcity, historic roosts had negligible seasonality in shedding, while new overwintering roosts exhibited shedding pulses in winter (Fig. 2A). Yet when food shortages occurred in the spring prior to sampling (Fig. 2B), both historic and new overwintering roosts displayed stronger shedding seasonality and amplitude the following winter. Further, the winter shedding amplitude
for new roosts was greater than historic roosts. Such patterns held after accounting for relative 
*Pteropus alecto* occupancy (Fig. 2C–D), which positively predicted HeV prevalence (Table 2).

**Heterogeneity in pathogen pressure**

Cumulative HeV pathogen pressure (i.e., area under each annual shedding curve) varied 
substantially across roosts and years (Fig. 3A). Our meta-analysis identified significant 
heterogeneity among AUC estimates ($I^2=0.93$, $Q_{24}=339.59$, $p<0.001$). When testing the 
ecological drivers of this variation, our GAM explained 40% of the deviance in pathogen 
pressure (Table 3). Whereas recent food shortages had little effect on AUC ($\beta=0.15$, $t=1.38$, 
$p=0.19$), newly established overwintering roosts had significantly greater pathogen pressure than 
historic roosts ($\beta=0.76$, $t=4.33$, $p<0.001$; Fig 3B). Similar results were obtained when adjusting 
for median annual and maximum winter fractions of *P. alecto* per roost (Table S2 & S3). In our 
primary model, the mean annual proportions of *P. alecto* also significantly and largely positively 
predicted AUC ($F=7.88$, $p<0.001$); similar results were obtained with median annual proportions 
of *P. alecto* but not winter maximum occupancy (Fig. S3; Table S2 & S3). Lastly, excluding the 
four AUC estimates from truncated time series mostly strengthened the associations between 
predictors (roost type, food shortage, *P. alecto*) and pathogen pressure (Fig. S4; Table S4–6).

**Pathogen pressure and HeV spillover**

Within the period of flying fox sampling (2012–2014), 12 spillover events occurred within 500 
km of our nine study roosts (Fig. 4A, Table S7). When aggregating spillovers within 50 km of 
each roost, our GAM explained 53% of the deviance and was primarily driven by spatial 
patterns, as AUC had a weak, nonlinear relationship with spillover ($\chi^2=4.74$, $p=0.11$). However,
when expanding the buffers between 100 and 500 km from each roost, our GAMs explained 29–45% of the deviance and predicted stronger associations between AUC and spillover (Table S8–S13). Generally, GAMs suggested a generally positive relationship between pathogen pressure and spillovers that was either maximized or saturated at intermediate-to-high AUC (Fig. 4B).

Discussion

Mechanistic understanding of cross-species transmission risk remains hindered by limited information on the relationships between reservoir host ecology, pathogen pressure, and observed spillover events [1,6,7,15]. By combining data on long-term ecology with the spatial and temporal distribution of infection, we here demonstrate that the ecological conditions experienced by reservoir hosts shape pathogen shedding. Prior work has shown that pulses of HeV excretion from flying foxes often occur in the Austral winter and that drier conditions in prior seasons are associated with peak annual shedding [20,21]. However, contextualizing these seasonal and climatic patterns with bat ecology here reveals that these periods of intensive virus shedding predominantly occur after food shortages and in new overwintering roosts in urban and agricultural habitats. By quantifying an aggregate metric of pathogen pressure, we also show that the accumulated intensity of HeV shedding provides distinct insights into these ecological drivers, as pathogen pressure is governed more by whether the roost is located in regions with native winter resources than by periods of recent food scarcity. Lastly, pathogen pressure was positively associated with cases of HeV in horses at a regional scale, which provides support for the spatiotemporal intensity of virus shedding as a mechanistic determinant of spillover risk.

Foremost, our findings emphasize that the ecological conditions experienced by reservoir hosts predict pronounced pulses of virus shedding and overall pathogen pressure. Across eastern
Australia, habitats for the winter-flowering plants that drive flying fox nomadism have been reduced through land clearance, in turn driving nutritionally stressed bats into novel urban and agricultural environments outside their typical overwintering range (Eby et al., in review) [27,32,36,37]. Prior work has proposed, but not tested, that HeV shedding from flying foxes is driven by this process [23–25,63]. Acute food shortages could produce cumulative effects with other energetic and seasonal stressors (e.g., pregnancy, thermoregulation), as well as reliance on poor-quality, non-native food in agricultural and urban habitats, to alter within-host dynamics of viruses in bats [22,23]. Prior work has suggested that the physiological demands of winter thermoregulation in parts of the *P. alecto* range could drive observed negative correlations between minimum temperature and urinary cortisol excretion [40]. Our results support the idea of cumulative stressors, as HeV shedding was greatest not only in winter but also in roosts that were established in novel overwintering habitats and after a food shortage in the prior spring. Increased viral shedding associated with suboptimal habitats or food shortages could be driven by immunosuppression, such that cumulative stressors may impair HeV tolerance and facilitate replication or allow latent infections to reactivate [25,64]. Recrudescent infection of henipaviruses in bats has been proposed to explain shedding pulses that coincide with stressors [24,25] and for seroconversions in captivity [65]. The mechanism driving the time lag between acute food shortages, which typically occur in spring, and increased HeV shedding in the following winter (i.e., in the subsequent 6–9 months; Fig. 1) remain unknown; however, the cumulative impact of multiple stressors (e.g., long-term nutritional stress, cold temperature, pregnancy) offers a potential explanation. Future studies, including immune assessments of wild bats and factorial experiments, will be critical to mechanistically understand the causal effect of spring food shortages, bat residency outside their winter range, dietary reliance on non-native
plants, and other energetic stressors (e.g., pregnancy) on subsequent winter pulses of HeV shedding. Such work would also provide foundational insights into how bats control zoonotic viruses more broadly, given likely effects of stressors on immunity and tolerance [66,67].

Pathogen pressure has been suggested to be a critical determinant of spillover risk in recipient hosts [1,6], but quantifying the spatial and temporal distribution of shedding in ways that facilitate downstream analyses has remained challenging. Here, we propose the area under annual shedding curves (i.e., AUC) as a meaningful metric to summarize pathogen output into the environment. AUC has previously been used to summarize the cumulative pathogen output from within-host dynamics (e.g., *Mycoplasma agassizii* intensity across individual tortoises [68]) and number of infected individuals (e.g., fungal infections across *Daphnia* populations [69,70]), which capture host infectiousness and local epidemic size, respectively, rather than the explicit infectious dose available to recipient hosts. For the latter, epidemic size has in turn been linked to local ecological conditions, such as lake temperature and host community composition [69,70]; however, such metrics have not been applied to replicate reservoir host populations to identify predictors of pathogen pressure. In one case study of a zoonotic pathogen reservoir, data on avian influenza virus prevalence in ducks were used to derive AUC across three regions of North America, but inference on its underlying ecological drivers was limited by few replicates [53].

In our analyses, AUC not only displayed substantial heterogeneity, but also varied with roost ecology in ways that differed from seasonal GAMMs. Whereas the timing and amplitude of shedding was driven both by roost type and prior food shortages, AUC was exclusively driven by roost type. This contrast could relate to the tension between a short but intense shedding pulse and a smoldering shedding dynamic with lower intensity. Short but intense shedding pulses observed after food shortages could produce similar AUC to the lower amplitude shedding that
occurred year-round in roosts without acute food scarcity. Such results emphasize how pathogen pressure can offer distinct insights into infection dynamics relative to shedding seasonality alone.

High pathogen pressure should theoretically have a pronounced effect on shaping the force of infection and the ultimate probability of spillover, given the hierarchical nature of cross-species transmission [1,6]. However, empirical support for pathogen pressure from reservoir hosts influencing disease cases in recipient hosts has been restricted by the rarity of spillover in many systems, such that evidence is mostly from temporal overlap between shedding events and outbreaks or broad-scale, regional analyses of reservoir infection and human disease data. For example, Marburg virus spillover to humans coincide with seasonal birth pulses of Egyptian fruit bats, when host shedding is most pronounced [71], and the density of bank voles seropositive for Puumala virus can also explain regional human incidence of nephropathia epidemic [72].

The relatively high frequency of HeV spillovers compared to less-frequent spillover in many other systems provides a tractable system for linking pathogen pressure and cross-species transmission [73]. Our analyses show that pathogen pressure (i.e., annual AUC) positively predicts observed spillovers within the broad, regional scales of flying fox movements (i.e., up to 500 km). As a caveat, no spillovers were recorded within typical nightly foraging ranges (i.e., 25 km) of the roosts monitored in our study region during the period of HeV surveillance [26,32]. Our findings therefore assume that the ecological conditions experienced by unsampled roosts in closer proximity to spillover events may be similar to those of our sampled roosts up to 500 km. As our patterns were consistent across a broad span of spatial scales relevant to flying fox mobility, our results suggest that the association between AUC and spillover are likely more affected by interannual variation in pathogen pressure, such as that driven by acute food shortages. Associations between pathogen pressure and spillovers were also mostly positive and
monotonic but generally not exclusively linear. Importantly, our measure of pathogen pressure accumulates processes in the spillover hierarchy—including reservoir host distribution, reservoir host density, infection prevalence, and infection intensity—up to and including shedding into the environment [1]. Downstream factors such as HeV survival in the environment and recipient host distribution and susceptibility may moderate effects of high pathogen pressure on spillover risk [6,74]. Additionally, short but high amplitude pulses of virus shedding, such as those observed in the year following acute food shortages, may ultimately provide a more sufficient HeV dose to horses, thus resulting in roughly equivalent spillover risks from moderate and high AUC [1,75].

Because summarizing the spatiotemporal intensity of infection both provided distinct insights into ecological drivers of pathogen shedding and predicted spillover at broad regional scales, we suggest quantifying pathogen pressure would be particularly tractable and useful in systems where recipient host exposure occurs following pathogen release into the environment. Such systems include but are not limited to bat filoviruses and coronaviruses, avian influenza viruses, and helminths, protozoa, and fecal-oral bacteria of various wildlife [4,71,76,77]. Careful sampling designs for these environmentally shed pathogens, such as under-roost sampling methods for bats, could facilitate estimating pathogen pressure and, in turn, spillover risks [78].

In conclusion, we show that the ecological conditions experienced by bat reservoir hosts shape the timing, magnitude, and cumulative intensity of zoonotic virus shedding in ways that subsequently predict observed spillover events. Importantly, such inferences were only possible by integrating both spatiotemporal data on infection with long-term studies of host ecology and behavior, which demonstrates the importance of long-term, spatially replicated studies of reservoir hosts for linking environmental change and zoonotic pathogen dynamics. Despite a long-standing recognition of spatial and temporal scale in ecological research [79], replication
across both axes remains challenging, particularly over relevant time intervals [80].

Spatiotemporal sampling is especially critical in the study of infectious disease [9,11], because pathogen shedding and transmission are both inherently spatial and temporal processes [63,81]. Connecting such data with changing ecology of wildlife further requires studies of abiotic and biotic correlates and host behavior and demography at similar or biologically meaningful spatial and temporal scales [7,14,82]. Here, the ecological conditions that predict HeV shedding from flying foxes were derived from behavioral data collected over approximately 25 years and from diverse sources [27,28,37] (Eby et al., in review). Although collecting this kind of ecological data will accordingly present logistical difficulties, the growth of national research networks, global community consortiums, and remote sensing, among other large-scale efforts, should facilitate similar approaches to link spatiotemporal data on both host ecology and infection [83].

In turn, careful attention to the ecology of reservoir hosts through long-term monitoring could facilitate improved early detection and preemptive management of zoonotic spillover events.

of the land upon which this work was conducted. We thank Hume Field, David Jordan, Peter Kirkland, and other co-contributors of the open access HeV dataset for data access and members of the Plowright lab for helpful feedback on previous versions of this manuscript.

Author contributions

DJB, PE, AJP, and RKP designed the study; PE, AJP, WM, and RKP collected, collated, and managed data; DJB analyzed data; and DJB wrote the manuscript with feedback from coauthors.

Data availability

All HeV shedding data and flying fox data used in this analysis are freely available from the Queensland government (CC BY 4.0; https://www.data.qld.gov.au/dataset/hev-infection-flying-foxes-eastern-australia) [20]. Ecological covariates of study roosts are provided in Table 1. Data on HeV spillovers within 500 km of our study roosts between 2012–2014 are provided to the nearest town in Table S4; finer-scale data are confidential as they identify individual properties.

Code availability

Code for estimating AUC from each annual time series per roost will be provided in the Supplemental Material upon acceptance.

Figures and legends

Figure 1. Spatiotemporal variation in HeV shedding for the nine flying fox roosts. Curves display the weekly proportion of HeV-positive urine pools, with roosts shown in order of latitude and colored by roost type. Ticks show sampling timepoints. Grey shading indicates regional acute food shortage events, and dashed lines indicate the Austral winter (i.e., June through August).
Figure 2. Fitted HeV urine pool prevalence and 95% confidence intervals from the most parsimonious GAMM with week, seasonal interactions with roost type and previous food shortages, the interaction between both factor variables, and an adjustment for categorical weekly *Pteropus alecto* occupancy. Weekly data are overlaid and colored by roost type. Thin lines show the fitted curves from the random factor smooth including each roost per year.
Figure 3. Variation in HeV pathogen pressure from flying foxes. The forest plot displays annual AUC estimates and 95% confidence intervals ordered by latitude and year; points are scaled by the number of sampling events per annual time series as weights. The horizontal axis uses a modulus transformation to accommodate wide upper bounds of some confidence intervals. Right displays fitted values and 95% confidence intervals for the GAM, with raw data (scaled by the number of sampling events per each time series) and modeled means colored by roost type. Transparency denotes AUC estimates derived from truncated annual time series (≤ 20 weeks).
Figure 4. Spatiotemporal variation in regional HeV spillovers during the flying fox surveillance period (2012–2014) and its relationship with pathogen pressure (AUC). (A) Maps display the annual distributions of spillovers (colored by year) in relation to the nine analyzed roosts. Modeled relationships between AUC and spillover counts are shown with fitted values and 95% confidence intervals from GAMs for 50, 100, 200, 300, 400, and 500 km buffers of each roost.
