Abstract

Ion currents through potassium channels are gated. Constriction of the ion conduction pathway at the inner helix bundle, the textbook ‘gate’ of Kir potassium channels, has been shown to be an ineffective permeation control, creating a rift in our understanding of how these channels are gated. Here we present the first evidence that anionic lipids act as interactive response elements sufficient to gate potassium conduction. We demonstrate the limiting barrier to K⁺ permeation lies within the ion conduction pathway and show that this ‘gate’ is operated by the fatty acyl tails of lipids that infiltrate the conduction pathway via fenestrations in the walls of the pore. Acyl tails occupying a surface groove extending from the cytosolic interface to the conduction pathway provide a potential means of relaying cellular signals, mediated by anionic lipid head groups bound at the canonical lipid binding site, to the internal gate.

30 Introduction

Until recently, it was thought that K⁺ channels must adopt a wide pore conformation to enable ion permeation and that gating entailed largescale conformational change^{1–3}. Native inward rectifier K⁺ (Kir) channels are constricted at the intracellular entrance in crystal structures^{4,5}, initially leading to the conclusion that these structures represent ‘closed’ pores⁵. The narrow conformation is not ‘closed’ in
 35 any physiological sense, however, as K⁺ is able to pass through an opening only marginally wider than its ionic diameter^{6,7}. This is tiny in comparison to the aperture size that would be needed to accommodate fully hydrated K⁺ ions and is achieved by transient depletion and replenishment of the K⁺ ion’s hydration shell as it negotiates the constricted opening, analogously to the dehydration-rehydration process as ions enter and exit the selectivity filter⁶. The capacity of K⁺ ions to move through a constricted inner
 40 helix bundle has re-opened the question of gating, or how Kir channels achieve controlled switching between conducting and non-conducting physiological states.

Eukaryotic Kir channels are regulated by phosphoinositide lipids⁸. A signature of the lipid-binding site is a five-residue basic sequence on the intracellular extension of the inner helices, typically starting with Arg-Pro (Supplementary Fig. 1). Kir channels are unresponsive until a phosphoinositide (PI) head group
 45 binds, after which they gate and conduct normally^{9,10}. While the binding site can accommodate other lipids¹¹ and detergents¹², only PI(4,5)P2 potentiates eukaryotic Kir channels, an exquisite specificity to phosphate substituents at positions 4 and 5 on the indole ring emphasised by the inability of the PI(4,5)P2 regioisomer PI(3,4)P2 to significantly potentiate activity in all but Kir6 (K_{ATP}) channels¹³, an assembly of Kir6 channels with sulfonylurea receptors. While prokaryotic Kir homologues do not share
 50 the complete basic sequence required for PI binding, a shorter Arg-Pro motif mediates analogous interactions with cellular phospholipids⁴.

It has been assumed that phosphoinositides exert their regulatory effects against a backdrop of the conventional gating model of conformational widening and narrowing of the pore. However, as Kir channels operate and gate without requiring a major conformational change⁶, we have sought an
 55 explanation for how ion flow through these channels is controlled. A clue is in the location of the regulatory phospholipid binding site, which straddles the membrane-cytosol interface. Structures show that phosphates of the inositol ring of PI(4,5)P2 interact with the Arg-Pro-basic motif^{5,11} and neighbouring polar residues. Lipid binding thus creates an extrinsic nexus connecting the transmembrane and intracellular domains. Binding of the PI(4,5)P2 head group is necessary for
 60 activation of Kir channels¹⁴ but the accompanying subtle structural remodelling at the membrane-cytosol interface evident in crystal structures offers no cogent explanation for the fine control over K⁺ flux. We have utilised the prokaryotic Kir channel KirBac3.1 to determine whether the acyl tails of bound lipids, protruding into the conduction pathway through fenestrations just below the selectivity filter, might represent key gating elements. Here we present evidence that in Kir channels, the limiting barrier

to permeation lies within the conduction pathway, formed by a collar of branched aliphatic side chains. We show that, by competing for individual side chains of the occluding collar, lipid tails occupying the fenestrations cause temporal dissipation of a steric barrier, enabling ions to pass.

Results

An internal barrier to K⁺ permeation

Several crystal structures of Kir channels reveal an internal occlusion comprising branched aliphatic side chains (Val, Ile, or Leu) pointing into the conduction pathway, the location along the molecular axis varying with subfamily (Supplementary Fig. 1). In KirBac3.1, the four Leu124 residues form a steric cluster physically occluding the conduction pathway, separating the cavity into upper and lower vestibules, while Tyr132 (at the inner helix bundle) forms a non-occlusive hourglass-shaped portal between lower vestibule and cytosol (Fig. 1a). As ion conduction is not gated at the Tyr132 collar, we considered the possibility that the Leu124 collar might provide the limiting barrier to K⁺ movement.

Reasoning that the chemistry of the contributing side chains determines their mutual affinity and propensity to form a steric barrier, we mutated the branched aliphatic residue Leu124 to the linear methionine, which is similar in both molecular volume and hydrophobicity, but more flexible. For comparison, we mutated the aromatic Tyr132 at the intracellular entrance to the branched aliphatic residue isoleucine. To evaluate the effect of the mutation on permeation, we reconstituted the L124M and Y132I mutant channels into liposomes and screened activity using a 9-Amino-6-chloro-2-methoxyacridine (ACMA) population assay (Fig. 1b), where a decrease in fluorescence due to protonation of the ACMA fluorophore reflects K⁺ conduction through liposome-reconstituted channels¹⁵. Mutation of Tyr132 to isoleucine (Y132I) reduced the magnitude of the fluorescence change, indicating diminished activity. Conversely, L124M assays showed enhanced channel activity, significantly outperforming KirBac3.1 in the fluorometric assay (Fig. 1c). Thus, at either collar, branched aliphatic residues presented an impedance to K⁺ permeation.

We determined a crystal structure of L124M in case the increased activity was due to structural distortion (such as forcing the inner helices apart) (Supplementary Table 1). The mutation was made on a background in which two native cysteines were mutated to serine (C72S-C262S; SCS) and thus we also determined a structure of the SCS background crystallised under the same conditions. The structures superimposed closely (rmsd = 0.33 Å for 100 Cα over the pore and slide helix, and 0.46 Å over all Cα), exhibiting only a minor deviation of the inner helix conformation (Supplementary Fig. 2a-c), whilst maintaining the constriction at Tyr132 (Supplementary Fig. 2d) and the integrity of the selectivity filter¹⁶ (Supplementary Fig. 2e). We also carried out single-channel recordings of the reconstituted L124M channels in lipid bilayers, revealing currents exhibiting the sub-conductance states typifying KirBac3.1⁴ (Supplementary Fig. 3).

To delve deeper into the factors underlying the effect of the Leu124 collar on permeation, we investigated the energetic barrier encountered by potassium ions at the Leu124 collar relative to Tyr132 using all-atom enhanced sampling molecular dynamics (MD) simulations across the Leu124 collar, moving K^+ along a one-dimensional trajectory between the upper vestibule and cytosol (Fig. 1d, Supplementary Fig. 4, Supplementary Table 2). The height of the free energy barrier (potential of mean force; PMF) at Leu124 is $\sim 13 \text{ kJ mol}^{-1}$, higher than that of 6 kJ mol^{-1} at Tyr132 but still not a significant barrier to ion passage. Perplexed by the absence of a barrier capable of preventing ion conduction, we carried out simulations on *in silico* mutants at both constrictions for comparison, focusing on the region of the conduction pathway between the lower vestibule and cytosol. A control Y132F mutant yielded a PMF of 5 kJ mol^{-1} at the phenylalanine collar, similar to the native tyrosine, whereas the isoleucine collar in Y132I created a higher energetic barrier to permeation (PMF = 33 kJ mol^{-1}) (Supplementary Fig. 4), consistent with the lower activity of Y132I in ACMA assays (Fig. 1c) and more in keeping with the PMF we had expected at the Leu124 collar. We also carried out simulations on the L124M mutant, using the crystal structure as a starting model, finding a negligible barrier to K^+ permeation at the collar.

Acyl chains attract aliphatic sidechains

We had anticipated a large energetic barrier at the leucine collar at residue 124 and were surprised to find a PMF only slightly higher than at the Tyr132 collar. We conducted and analysed the unrestrained simulation data for factors that might explain this. All structures capturing K^+ passing the Leu124 collar were extracted from MD simulations and analysed. In every instance, we observed extended fatty acyl chains of lipids occupying fenestrations near the midpoint of the lipid bilayer (Fig. 2c), a phenomenon also observed in crystal structures (Fig. 2a, Supplementary Fig. 2f). The carbon chains moved naturally into the fenestrations during the initial MD equilibration steps. Significantly, each K^+ permeation event occurred in response to interaction of the fatty acid termini with Leu124 (Fig. 2b). A combination of mutual aliphatic attraction and lipid movement drew the leucine side chains away from the conduction pathway, resulting in limited dissociation of the tetrameric Leu124 cluster and creating a peripheral opening of sufficient diameter to allow K^+ to pass (Fig. 2c, Supplementary Fig. 5a).

Ions slipped past the Leu124 collar when the mean distance across the opening increased to an asymmetric aperture of approximately $5 \text{ \AA}$ in diameter (van der Waals' accessible surface) (Fig. 2d, Supplementary Fig. 5), with K^+ retaining a coordination shell of four to five water molecules as it passed through (Fig. 2e). The interaction of lipidic tails in the fenestrations with Leu124 had only minor effects on the pore structure, with rotamer changes of L124 accommodated by small ($<1 \text{ \AA}$) local perturbations of the inner helix. The action of aliphatic lipid termini in disrupting the tight Leu124 collar thus rationalises the lower-than-expected energetic barrier to K^+ permeation.

Lipid occupancy determines conduction

To analyse the impact of fenestration lipids on the Leu124 collar, we calculated the probability density of lipid termini within 5 Å of Leu124 side chains over all simulation frames (Fig. 3a), observing up to five lipid termini (a few examples had two lipid termini occupying a fenestration) per tetrameric channel. The highest probability density in the distribution corresponded to two lipids per tetramer. However, even a single fenestration occupied by lipid engaging Leu124 conferred a small probability of an opening of sufficient breadth to allow potassium to pass the collar (Fig. 3a).

To determine the effect of excluding lipid tails from the fenestrations on the energetic barrier to permeation at the Leu124 collar, we occluded the fenestrations by altering the rotamer of a neighbouring tyrosine (Tyr57) from *trans* (χ_1 (N-C α -C β -C γ) = 180°) to a *gauche* (χ_1 = -60°) conformation; an approach requiring minimal imposition of constraints and negligible adjustment to surrounding residues. Notably, simulations of wild type channels show the *gauche* rotamer is present 11% of the time (Supplementary Fig. 6). The number of *gauche* rotamers affected width of the aperture at the Leu124 collar; with a tight distribution of occluded pores when all four Tyr57 were *gauche*, and an increasingly variable shape as the number of *trans* rotamers increased (Supplementary Fig. 6). Importantly, no K⁺ ions passed the Leu124 collar in simulations where all four fenestrations were blocked by a *gauche* conformation of Tyr57. In this case, the energetic barrier faced by K⁺ at the Leu124 collar was a prohibitive 41 kJ mol⁻¹, substantially greater than the energetic barrier of 13 kJ mol⁻¹ observed when lipids are allowed to naturally interact with Leu124, and even greater than that observed in the Tyr132 collar isoleucine mutant Y132I (Fig. 1d, Supplementary Fig. 4). It is thus the action of lipid tails on Leu124 that dissipates the energetic barrier and allows permeation.

We reasoned that if the leucine collar is the primary permeation gate and the role of the lipid tails is to competitively displace individual leucine side chains, thereby compromising the collar, lipids should not be required for permeation in the L124M mutant with its labile methionine sidechains. We thus simulated the L124M mutant under the same conditions as KirBac3.1, excluding lipid from all four fenestrations (4 x Tyr57 *gauche*) for comparison. Indeed, L124M with all four Tyr57 adopting *gauche* rotamers appeared as effective at conducting K⁺ as wild type KirBac3.1 with all Tyr57 side chains *trans* (Supplementary Fig. 6), indicating that the interaction with aliphatic lipid tails in wild type is only required because of the inflexible steric occlusion created by Leu124 residues. The branched aliphatic leucine side chains comprising the native Leu124 collar thus form a 'gate-able' barrier to conduction, operated by chemically similar aliphatic lipid chains in a competitive tug-of-war.

To cross-validate this experimentally, we mimicked isolated lipid tails using alkyl-methylthiosulfonate (alkyl-MTS) reagents, derivatising a native cysteine residue (Cys119) located near the midpoint of the bilayer at the outer opening to the fenestration on an otherwise cysteine-less background (SCS); the same background as used for L124M. All Cys119 MTS-derivatives contain the Leu124 collar (*i.e.* not

L124M). Derivatisation was verified by gel shift assay of samples after reacting unlinked cysteines with 5 mM methoxy PEG maleimide (Supplementary Fig. 7). Two reagents, the substituents differing by four carbons in length, were employed; reasoning decyl-MTS should be sufficiently long to fully engage Leu124, while hexyl-MTS should not. We hypothesised that at high occupancy, hexyl chains would block the fenestrations, diminishing activity if lipids are mediators of conduction but leaving activity unaffected if they are not. ACMA fluorimetric population assays on the reconstituted derivatised channels showed bound decyl chains (C119-decyl) increased activity relative to wild type, consistent with Leu124-lipid interaction, while the hexyl reagent (C119-hexyl) reduced function (Fig. 3b, Supplementary Fig. 8, Supplementary Tables 3, 4), consistent with exclusion of membrane lipid. The data indicate that ion permeation is contingent upon lipid tails being of sufficient length to reach the occlusion.

To directly compare the effect of alkyl derivatisation on the activity of individual channels, we performed electrophysiological recordings in artificial bilayers on channels derivatised with one of three MTS-reagents to titrate the effect of chain length; C119-decyl, C119-octyl and C119-hexyl. Current-voltage (I-V) curves from single channel recordings of the spermine-sensitive channels show the decyl, octyl and hexyl-derivatised channels remain fundamentally similar (Supplementary Fig. 9). Analysis of the recording data using Hidden Markov Modelling shows that C119-decyl has a much higher probability of operating at maximal conductance during activation bursts (mean open probability, $P_o = 0.69$) than C119-octyl ($P_o = 0.41$) or C119-hexyl ($P_o = 0.46$) and is more likely to be fully open than operating in a lower amplitude substate (P_s). Substitution with the shortest alkyl chain, C119-hexyl, yields a channel most likely to be operating at a lower conductance substate level, while C119-decyl is the least likely to operate at substate level (Fig. 3c, Supplementary Fig. 9). We note that relative to the C119-derivatised channels, the L124M mutant has the highest probability of being fully open, consistent with its ability to function in the absence of fenestration-bound lipid (Supplementary Fig. 3).

To verify that the C119-decyl substituents were indeed emulating the effect of lipid, we ran unrestrained MD simulations as before, estimating the probability density of fenestration occupancy by decyl substituents and the corresponding effect on the Leu124 aperture. As lipid tails were also occasionally observed in fenestrations, the total number of aliphatic chains entering the fenestrations were enumerated. Most usually, the C119-decyl tail engages a Leu124 side chain (*i.e.* lies within 5 Å of any atom of Leu124) in three of the four fenestrations (Fig. 3c, Supplementary Fig. 10a-c). The increase in occupancy relative to wild type channels (Fig. 3a) may be due to covalent binding of the decyl substituents at the fenestration entrance. In C119-hexyl, by contrast, the hexyl chains partially enter the fenestrations but rarely far enough to engage Leu124; the highest probability density is at zero (no engagement) with about 3 % of structures with a single Leu124 engaged by a hexyl substituent. The more likely outcome is displacement of hexyl substituents by lipid termini from the bilayer (~19 %).

(Supplementary Fig. 10d-f). Both scenarios can result in a breach of the steric cluster, but very few ion permeation events are observed.

Anionic lipids are tightly retained

Our functional experiments indicated that, in the same manner as human Kir channels are potentiated by phosphoinositides, the prokaryotic Kir channel has a requirement for anionic lipids. To investigate the requirement for anionic lipid head groups, we carried out 100 μ s coarse-grained MD simulations on KirBac3.1 embedded in membranes comprising a 1:1:1 ratio of phosphatidylcholine:phosphatidylserine:phosphatidylglycerol (PC:PS:PG). We evaluated differences in protein-lipid association by estimating the probability density distribution of lipid head groups surrounding the pore in the inner bilayer leaflet (Fig. 4a). The PC head groups were broadly distributed, forming a diffuse halo at a radial distance of 25 - 45 Å from the principal molecular axis, which defines the centre of the simulation system. The heads of the anionic lipids exhibited a much tighter distribution, enriched at a radius of ~25 - 30 Å, which is comparable to the distance between the PI(4,5)P2 head group at the canonical lipid binding site and the molecular axis in structures of Kir2.2 (e.g. PDB entry 3SPI)¹¹. Coupled with evidence of 4-fold symmetry in the distribution of the anionic lipids, the data suggest PS or PG are likely to occupy the canonical lipid binding site, whereas PC loosely associates with the channel. Lipids in the canonical binding site are better placed to occupy the surface cleft connecting each binding site with a fenestration (Fig. 4b, Supplementary Fig. 11).

We utilised mass spectrometry methodology to identify the lipids carried through in purification of wild type KirBac3.1 expressed in *E. coli*. The native mass spectrum of purified KirBac3.1 displayed an adduct peak series with an average additional mass of 765 Da, relative to the native tetramer (Fig. 4c). Further lipidomics analysis confirmed the identity of the lipid adducts as phosphatidylethanolamine (PE) and PG, with PG adducts being enriched (Fig. 4d). Examining the fatty acyl chain length of lipids co-purifying with KirBac3.1 revealed enrichment of species with long acyl chains (> 34 total carbons over the two acyl chains) over their proportions in *E. coli* lipid mixes, consistent with preferential binding of long chain fatty acids (Fig. 4e).

Discussion

We previously demonstrated that Kir channels conduct K⁺ through a very narrow pore⁶, re-opening the question of how ion permeation is controlled in these channels. Here, in a major conceptual shift, we present evidence that lipid molecules tightly associated with Kir channels operate an occlusive barrier between the selectivity filter and cytosolic portal. All crystal structures of native KirBac3.1 show the conduction pathway is occluded by a Leu124 cluster, indicative of a favoured low-energy state.

While the function of many K⁺ channels is known to be enhanced by the presence of anionic lipids¹⁷, notably PI(4,5)P2¹⁸, the interaction of Kir channels with anionic lipids is obligate, and binding of the

anionic moiety is essential for activation. It is insufficient for function, however, and here we show that a steric barrier, comprising branched aliphatic side chains, is operated in a stochastic manner by fatty acyl termini. The acyl chains insinuate into the conduction pathway to competitively sequester leucine side chains, compromising the leucine cluster to create an aperture sufficiently wide for K^+ to pass. We observed that potassium ions were coordinated by four to five water molecules as they passed the Leu124 collar. This is higher than the coordination number of ions passing the Tyr132 collar at the inner helix bundle constriction, in which the aperture is correspondingly smaller⁶, illustrating a key energetic difference between constrictions comprising branched aliphatic and aromatic side chains; leucine forms a hydrophobic occlusion while tyrosine stabilises partially hydrated K^+ by cation- π coordination, meaning fewer coordinating water molecules are required to shield the K^+ charge.

We were able to experimentally manipulate the steric occlusion at Leu124 by two means, mutagenesis and lipid mimicry. In simulations, the L124M mutant was able to conduct even when lipid tails were prevented from entering fenestrations, demonstrating the unbranched aliphatic residue methionine does not form a significant barrier to permeation; L124M is essentially ungated. We were able to modulate activity by changing the length of the covalently associated lipomimetic substituents relative to the distance between Cys119 and Leu124. This rationalises the preferential binding of lipids with long acyl chains revealed by mass spectrometry analysis.

We have established that the aliphatic termini of lipids are as essential to function as the anionic head group, and suggest these remote functional moieties, half a bilayer apart, exert allosteric control over conduction. While our experiments show it is not necessary that the remote functions are carried out by the same lipid molecule, under physiological conditions it is most likely to be the case, facilitated by the natural hydrophobic surface crevices connecting the head-binding site to the centre of the bilayer. When the head and tail involved are part of the same lipid, a resultant connection between intracellular surface and internal constriction is potentially capable of providing the control over gating that is required for maintaining neural and organ function in higher organisms. In eukaryotic Kir channels, contacts made by PI(4,5)P2 link the pore and intracellular domains, subtly rearranging the interfacial region^{4,11} and potentiating the channel. In the light that intracellular domains of Kir channels move independently, rotating and re-orienting relative to the pore^{4,19,20}, it is tempting to speculate that, through the extrinsic lipid connections, interdomain motions manifest in the depth of penetration of the lipid termini into fenestrations, and in turn to their capacity to 'tug' a blocking leucine side chain.

Moreover, we have demonstrated using MD simulations that the number of lipids engaging Leu124 side chains is correlated to opening at the Leu124 collar. When lipid entry is hampered by partially or fully blocking the fenestrations (C119-hexyl or Tyr57 '*gauche*') we observe fewer, or no, permeation events, respectively. Moreover, the phenomenon of conduction substates in K^+ channels is not well understood,

and our data hint that the conduction substates we observe in single-channel recordings may have their origins in a fluctuating number of Leu124 side chains engaged by the termini of alky chains.

Conclusions

Here we have introduced the concept that control over permeation in Kir potassium channels is achieved by an interactive relationship between the channel and bound phospholipids, demonstrating that the aliphatic termini of lipids, acting on a steric occlusion within the conduction pathway, lower the free energy barrier to ion permeation. Based on this concept, we have been able to enhance and attenuate activity according to prediction, verifying the nature, site, and operating mechanism of a permeation gate. In a physiological context, active Kir channels must form a specific association with lipids with fatty acyl substituents of sufficient length to extend from a tightly bound anionic head group at the intracellular surface to the conduction pathway, entering via fenestrations in the pore walls. Our findings sit within the emerging context of a general sensitivity of ion channels to phosphoinositides^{18,21}, and anionic lipids in general¹⁷ analogous fenestrations have been reported in other ion channel families²², suggesting the concept of specifically bound phospholipids as allosteric gating elements may be more widely applicable.

Figure 1. Branched aliphatic side chains form a barrier to ions within the conduction pathway. (a) Ribbon representation of the KirBac3.1 pore (cyan); for clarity, only two subunits are shown. The side chains of Leu124, Tyr132 and Thr96 are depicted (yellow sticks). A scale bar indicates the distance (Å) from the centre of mass of Thr96. SF indicates the location of the selectivity filter. Insert shows a longitudinal section depicting the accessible surface of the pore interior, highlighting the steric barrier provided by the Leu124 cluster. Potassium ions at binding sites are depicted in purple. **(b)** Schematic of the ACMA assay. A lipid-soluble proton-sensitive dye (ACMA) is equilibrated with proteoliposomes (green circle) in isotonic solution (K^+_{in}/Na^+_{out}), prior to addition of the protonophore, carbonyl cyanide m-chlorophenyl hydrazone (CCCP). Protons moving into the liposome via CCCP bind ACMA to form ACMA-H⁺, which does not fluoresce, resulting in a decrease in total fluorescence emission. Proton influx is balanced by K⁺ efflux through Kir. Protonated ACMA cannot pass out through the membrane. Limiting fluorescence is determined by addition of the specific K⁺ ionophore valinomycin. The total fluorescence change measured in the assay is summed from individual proteoliposomes. **(c)** Summary functional assay data for the Leu124 and Tyr132 point mutants presented as mean ± SEM. **(d)** PMF along the molecular axis, oriented to match the inset in panel A. Distances along z are relative to the centre of mass of the four Thr96 sidechains.

Figure 2. Competition for the aliphatic side chains of Leu124 by extended alkyl chains in the fenestrations is sufficient to disrupt the leucine collar and allow K⁺ to pass. Materials and Methods

Materials

Detergents are from Anatrace, lipids from Avanti Polar Lipids and all other reagents, unless otherwise stated, purchased from Sigma Aldrich. Kirbac3.1 mutant cDNA was purchased from Genscript. Chromatography columns and resins are from GE Healthcare.

Protein preparation

Kirbac3.1 was expressed in C41(DE3) (Lucigen Cat# 60442) *E. coli* at 18°C for 18 hours. Cells were harvested and resuspended in 20 mM TRIS pH 8.0 and 150 mM KCl containing EDTA free Complete Protease Inhibitor (Roche) followed by lysis by two passes through a STANSTED SPCH-10 high pressure homogeniser from Homogenising Systems (UK) at 100 MPa. Membranes were harvested by centrifugation at 265,000 x g for 60 min at 4°C and the protein solubilised in 100 ml of 20 mM TRIS pH 8.0, 150 mM KCl, 1 mM PMSF and 1% (w/v) 3,12-Anzergent for 45 min. Insoluble material was removed by centrifugation. Imidazole to 20 mM was added to the supernatant, which was loaded on a 5 ml IMAC HiTrap column (GE) charged with Co²⁺. Protein was eluted with a linear gradient of imidazole, up to 500 mM, in buffer containing 20 mM TRIS pH 8.0, 500 mM KCl, 0.1 mM PMSF and 0.05% (w/v) dodecyl-β-D-maltopyranoside (DDM). Fractions containing KirBac3.1 were concentrated in a 100 kDa molecular weight cut-off centrifugal concentrator (Millipore) and applied to a Superdex 200 10/30 column (GE) equilibrated with 20 mM TRIS pH 8.0, 150 mM KCl, 0.02% (w/v) DDM; with 0.5 mM TCEP added to samples that did not require further chemical derivatisation. Fractions corresponding to the KirBac3.1 tetramer were concentrated with a 100 kDa centrifugal concentrator (Millipore) to between 10 and 40 mg ml⁻¹, snap frozen in liquid N₂ and stored at -80 °C as single use aliquots.

MTS derivatisation and evaluation

KirBac3.1 mutants were diluted to 1 mg ml⁻¹ in crosslinking buffer (20 mM TRIS pH 8.0, 150 mM KCl and 0.02% (w/v) DDM) and crosslinked by addition of decyl or hexyl (MTS), to 4 mM or 5 mM respectively, followed by incubation at room temperature for 2 hours with gentle agitation. Excess MTS reagents were removed with Micro Bio-Spin 6 columns (Bio-Rad) equilibrated in crosslinking buffer. The tetramer was re-purified by size exclusion chromatography with a Superdex 200 10/30 column (GE) equilibrated with the crosslinking buffer. Fractions corresponding to the KirBac3.1 tetramer were recovered and concentrated with a 100 kDa centrifugal concentrator (Millipore) to between 10 and 20 mg ml⁻¹, snap-frozen in liquid N₂ and stored at -80°C as single use aliquots until required.

To evaluate the completeness of the reaction we modified the method of Accardi²³. An aliquot (11 µl) of the reacted protein was denatured by incubation with 44 µl 100% (v/v) acetone stored at -20°C. The sample was incubated overnight at -20°C, before pelleting via centrifugation at maximum speed at 4°C in a benchtop centrifuge. The supernatant was carefully removed, and the pellet air-dried. Methoxy-

polyethylene glycol maleimide 5000 (mPEG5K) was made up to 5 mM in 8 M Urea and 2% (w/v) SDS before the protein pellet was resuspended in 10 μ l mPEG5K and incubated for 1 hr at room temperature. Samples were then analysed via SDS-PAGE. KirBac3.1 runs as a monomer on SDS-PAGE. Free cysteines result in a gel-shift of the band by the approximate mass of the mPEG5K, whereas derivatised cysteines are protected from PEGylation and migrate at the same rate as the wildtype.

Crystallization and Data Collection

KirBac3.1 SCS mutants at a concentration of 4 mg ml⁻¹ were crystallized in sitting drops by vapor diffusion at the Bio21 C3 crystallisation facility in Parkville against 2.5% PEG 4,000; 2.5% PEG 8,000; 10-21% PEG 400; 90 mM HEPES pH 7.5, 1 mM TCEP and 50 mM EDTA, or 10 mM CaCl₂. The crystals were cryoprotected prior to data collection by the addition of TMAO pH 8.0 to ~2 M. All crystallographic data were collected at beamline MX2 at the Australian Synchrotron using Blu-Ice²⁴.

Structure Determination and Refinement

Crystallographic data were processed and scaled using XDS²⁵ and reduced using the CCP4 suite²⁶. Electron density in all structures was phased by molecular replacement, using PHASER²⁷ as implemented in the CCP4i suite. A molecular replacement model for the wild type structure was derived from previous protein data bank entries from our group. Electron density maps for the structures were B-factor sharpened. Model building was carried out using COOT²⁸ and refinement using PHENIX²⁹. Atomic coordinates were iteratively refined by maximum likelihood, and simulated annealing procedures applied, alternating positional refinement cycles with individual B-factor refinement. Occupancy was refined for ligands, ions and residues with alternate conformations. Refinement was monitored according to the decrease in R_{free} . A number of residues in each structure were omitted or had side chains truncated due to positional disorder. Statistics are presented in [Supplementary Table 1](#).

Molecular Dynamics

The 2.0 Å crystal structure of native KirBac3.1 (PDB 6O9U)⁶ was used as an initial model for wild type, Y132 mutants, C119-decyl, C119-hexyl and Y57-related simulations. The 2.7 Å crystal structure of the L124M mutant was used for L124M simulations. The whole simulation systems were prepared using the CHARMM-GUI Membrane Builder server³⁰, with N- and C- terminal residues patched as standard termini. Transmembrane pores (residues 33 to 138) were embedded within a standard POPC bilayer, each containing 162 lipids, using the replacement method. Additionally, each starting model contained five potassium ions: three sites within the selectivity filter (S1, S3, S4) and two in the internal cavity (near the selectivity filter). One additional potassium ion was placed in the lower cavity. Thirty water molecules were also placed in the cavity. The simulation cells comprised approximately 60,000 atoms, of which approximately 30,000 were water molecules, in a box of dimensions 8.2×8.2×8.4 nm³. TIP3P water parameters were used to solvate all systems and all ionisable residues were assumed to be in their dominant protonation states at pH 7. Sufficient K⁺ and Cl⁻ ions were introduced by replacement of

water molecules to bring the systems to an electrically neutral state at an ionic strength of 0.15 M. The principal axis of the pore was aligned along the z-axis.

All simulations were performed using the GPU-accelerated GROMACS software package (version 2020.1)³¹ and CHARMM36m force field³². CMAP corrections were applied for all components; all atoms including hydrogen atoms were included. CGenff³³ program was used to parameterize the C119-decyl and C119-hexyl residues. Dihedral restraints were applied onto the dihedral N-CA-CB-CG in Y57 at -65±10° with harmonic force constant of 1000 kJ mol⁻¹nm⁻² in Y57-related simulations to maintain a *gauche* rotamer. To obtain the equilibrated channel-ion-solvent-membrane complex, an elongated CHARMM-GUI Membrane Builder preparation protocol was followed. Steepest descent energy minimization was followed by six sequential steps of equilibration with a gradual decrease in the restraining force applied to different components. After 101.5 ns NVT and NPT equilibrations, the resulting structures were utilized in steered molecular dynamics (SMD) or directly in unrestrained MD. The LINCS³⁴ algorithm was applied for resetting constraints on covalent bonds to hydrogen atoms, which allowed 2 fs time steps for MD integration during the entire simulation. The particle-mesh Ewald³⁵ algorithm was used for calculating electrostatic interactions within a cut-off of 12 Å, with the Verlet grid cut-off-scheme³⁶ applied for neighbour searching, using an update frequency of 20 and a cut-off distance of 12 Å for short-range neighbours. A 12 Å cut-off was applied to account for van der Waals interactions, using a smooth switching function starting at 1.0 nm. Periodic boundary conditions were utilized in all directions. During the equilibration stages, the temperature was maintained at 303.15 K using a Berendsen-thermostat³⁷ with a time constant of 1.0 ps. Protein, membrane and ion-water groups were treated independently to increase accuracy. The pressure was maintained at 1.0 bar by semi-isotropic application of a Berendsen-barostat³⁷, with a time constant of 5.0 ps. During steered molecular dynamics, the temperature was maintained at 303.15 K using a Nose-Hoover-thermostat³⁸ with a time constant of 1.0 ps, with protein, membrane and ion-water groups treated independently, with the pressure maintained at 1.0 bar using the Parrinello-Rahman-barostat³⁹ semi-isotropically, with a time constant of 5.0 ps and compressibility of 4.5 × 10⁻⁵ bar⁻¹. The umbrella sampling method was used to calculate the potential of mean force (PMF) before ions passed through the leu124 collar until fully into solvent. The reaction coordinate of a potassium ion was defined relative to the center-of-mass (COM) of the four Thr96 residues at the base of the selectivity filter along the z direction. The initial structures for umbrella sampling were extracted from the pulling SMD trajectory. Pulling potentials were set for two discrete pulling groups: the potassium ion in the upper cavity and four Thr96. The pulling geometry was direction-periodic, with a harmonic force constant during umbrella pulling of 3000 kJ mol⁻¹nm⁻². The rate of change was 0.2 Å ns⁻¹ in each case. Although subjecting a target ion to pulling forces, a flat-bottomed position restraint was applied to the ion to restrain it within a cylinder with a radius of 1 Å running parallel to the z axis. Each umbrella sampling window was simulated for 310 ns or 200ns dependant on the total sampled length of reaction coordinates. The windows were centred at

~0.5 Å intervals along the z axis, covering the range from 16.5 to 36.5 Å relative to the centre-of-mass of the four Thr96 residues; during umbrella sampling the flat-bottomed position restraint on pulled ion was removed. A static external electric field with a strength of 0.05 V nm⁻¹ was applied along the membrane normal direction toward the cytoplasmic domain side in steered molecular dynamics and umbrella sampling. Final PMF profiles were calculated using gmx-wham⁴⁰ and the statistical uncertainties estimated via Bayesian bootstrap analysis with 200 bootstraps and a tolerance of 10⁻⁶. The number of water oxygen atoms within a prescribed cut-off distance of 3.0 Å of the target ion along traveling reaction coordinate was calculated using VMD⁴¹. For unrestrained MD, the number of lipids and/or C119-decyl/hexyl alkyl chains within cut-off distance of 5.0 Å of the sidechain atoms of leu124 was also calculated using VMD. All probability density profiles and two-dimensional histograms were constructed using the ggplot2⁴² package in the R software package.

All unrestrained simulations were carried out in an electric field at 50 mV nm⁻¹; in each, simulations were run over 200 ns. The interchangeable diagonals, edges, area were statistically analysed as D1 and D2 couplets for structures extracted with 10 ps intervals. All hexbin figures were symmetrized by exchanging the indices of diagonals; that is, the couplets of (D1, D2) were duplicated in the form (D2, D1). All probability density functions were calculated using the ggplot2 package in R software and integration calculations were performed the Grace plotting tool.

Coarse-grained simulations were performed using the GPU-accelerated GROMACS software package (version 2020.1)³¹ and martini22 force field⁴³. Martini2.2 parameters were using to treat protein section, and Martini2.0 parameters for lipids and ions and non-polarizable water. CHARMM-GUI Martini Bilayer Maker was used to construct simulations system. Transmembrane pores (residues 33–138) were embedded into lipid bilayer has 34% POPC, 33%POPG and 33%POPS in both leaflets. 800ns NVT and NPT equilibration steps with a gradual decrease in the restraining force on channel atoms were taken prior the each 20 μs production MD. Five replicates in total were run. The gmx-densmap program was used to calculate the planar distributions of lipid head groups.

Summarised experimental parameters can be found in [Supplementary Table 2](#).

KirBac Liposome Reconstitution

Lipids (50% 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine:POPC, 5% 1-palmitoyl-2-oleoyl-sn-glycero-3-phospho-L-serine:POPS, 45% total *E. coli* lipids:TECL in the ratio POPC:TECL:POPS 50:45:5) were dissolved in chloroform:methanol (65:35), dried to a thin film under N₂ and residual solvent removed by lyophilization overnight. Water was added to a final lipid concentration of 25 mg ml⁻¹ followed by incubation at 37°C for 1 hour and 5 freeze/thaw cycles. An equal volume of 2x inside buffer (IB) was added to give a final buffer composition of 20 mM Tris-HCl pH 8.5 and 150 mM KCl followed by

extrusion to 400 nm (two rounds of 11 passages through the filter) in a mini-extruder (Avanti Polar Lipids) preheated to 65 °C. In some experiments NaCl was substituted for KCl.

For reconstitution, dodecyl- β -maltopyranoside (DDM) was added to a 1:8 molar detergent:lipid ratio to liposomes and incubated for 15 minutes at room temperature followed by the addition of protein to a protein:lipid molar ratio of 1:555 and incubation for 1 hour at room temperature.

Excess detergent was removed by passing 80 μ l of proteoliposomes through G50 resin (settled bed volume 3 ml) equilibrated in inner buffer (IB), followed by elution with IB. Further detergent removal was accomplished by dilution of liposomes to a final volume of 1.5 ml by centrifugation at 91,000 x g for 1 hour at 25°C. The liposome pellet was resuspended in 100 μ l IB, centrifuged at 3000 g for 3 minutes and any precipitate discarded. Liposome size uniformity was assessed using dynamic light scattering (Zetasizer – Malvern Instruments) and protein reconstitution by SDS-PAGE using known concentrations of KirBac3.1 in DDM as standards. Amount of protein added was optimized using wild type KirBac3.1 to achieve an average of 0.3 functional channels per liposome, with equivalent protein:lipid ratios used for the crosslinked experiments.

Liposomal Fluorimetric assay

Fluorimetric liposome assays were performed within 24 hours of KirBac reconstitution. Each 5 μ l aliquot of prepared liposomes was diluted to a final volume of 110 μ l in outside buffer (OB: 20 mM Tris-HCl pH 8.5 and 150 mM NaCl), resulting in a final buffer composition of 20 mM Tris-HCl pH 8.5, 143.2 mM NaCl and 6.8 mM KCl. The pH sensitive dye 9-amino-chloro-2-methoxyacridine (ACMA) was added to a final concentration of 2 μ M from a freshly prepared 200 μ M stock in 100% (v/v) ethanol. Fluorescence emission at 483 nm (excitation at 419 nm) was monitored over time with path lengths of 2 and 10 mm for excitation and emission, respectively. Baseline fluorescence was monitored for 3 minutes before the proton specific ionophore carbonyl cyanide m-chlorophenyl hydrazine (CCCP) was added (t=0) to a final concentration of 9 nM from a freshly prepared 500 nM stock prepared in OB. A decrease in fluorescence is observed when the membrane is permeable to K⁺. After 35 minutes (t=35), the K⁺ specific ionophore was added to 20 nM from a freshly prepared 2 μ M stock made up in 100% (v/v) ethanol. The assay was allowed to reach a final electrochemical equilibrium over a further 20 minutes. In some experiments, the K⁺ channel blocker spermine was added to a final concentration of 500/1000 μ M in IB/OB before the establishment of the fluorescence baseline. Control liposomes were prepared identically to proteoliposomes with the exception of the addition of an equal volume of crosslinking buffer in place of protein.

All fluorescence experiments were normalized to the fluorescence measured at t=0, which represents maximal fluorescence (100%); and the fluorescence measured after the addition of valinomycin, which represents the minimal fluorescence where all liposomes have equilibrated (0%). A first-order

exponential decay was fitted from $t=0$ to $t=35$ to determine the change in fluorescence due to K^+ flux through reconstituted KirBac channels.

Single Channel Measurements

KirBac3.1 proteoliposomes were incorporated into planar lipid bilayers separating two aqueous chambers (*cis* and *trans*). Bilayers were produced using the Mueller method⁴⁴. Bilayers were formed across an aperture in a delrin cup with diameter 150-250 μm using a lipid mixture of phosphatidylethanolamine, phosphatidylcholine and phosphatidylserine (7:2:1 wt/wt, Avanti Polar Lipids) in *n*-decane (50 mg ml^{-1} , ICN Biomedicals). The *cis* chamber contained 250 mM KCl and 1.0 mM CaCl_2 and the *trans* chamber contained 50 mM KCl and 0.1 mM CaCl_2 . Proteoliposomal fusion with bilayers was initiated by adding 5 μl aliquots of the proteoliposome preparation (described above) to the *cis* bath whilst stirring. During experiments, the composition of the *cis* solution was altered by a perfusion system⁴⁵ that allowed exposure of single channels to additions of spermine or KCl/NaCl substitutions within ~ 1 s. All solutions were pH buffered using 10 mM N-tris[hydroxymethyl] methyl-2-aminoethanesulfonic acid (TES; ICN Biomedicals) and titrated to pH 7.4 using KOH (ICN Biomedicals). KCl was obtained from Aldrich and CaCl_2 from BDH Chemicals. Experiments were carried out at room temperature ($23 \pm 2^\circ \text{C}$).

Data Acquisition and Analysis

Electric potentials expressed as *trans* relative to *cis* at virtual ground. Control of the bilayer potential and recording of unitary currents was done using an Axopatch 200B amplifier (Axon Instruments Pty, Ltd). Channel currents were digitized at 50 kHz and low pass filtered at 5 kHz. Before analysis the current signal was re-digitized at 1 kHz and low pass-filtered at 500 Hz. Channel substate analysis was carried out using the Hidden Markov Model (HMM)⁴⁶. The algorithm calculates from the raw signal the most likely amplitude histogram, the idealised, three-level, current time course with background noise subtracted and the transition-rate matrix using maximum likelihood criteria.

Native Mass Spectrometry

KirBac3.1 protein was buffer-exchanged to 200 mM ammonium acetate (pH=8.0) with 0.5% C8E4 (2 $\times$ CMC) using a Biospin-6 column (BioRad). The protein sample was loaded into a gold coated needle prepared in-house and analysed on a modified Q-Exactive mass spectrometer (Thermo Fisher Scientific). The typical MS settings were spray voltage of 1.3 kV, source fragmentation of 50-150 V, HCD collision energy of 50-200 V and resolution of 17500 at m/z 200.

Lipidomics

KirBac3.1 co-purified lipids and *E. coli* total lipids were analysed using mass spectrometry based lipidomics⁴⁷. Briefly, protein was digested with trypsin overnight at 37°C , lyophilized and re-dissolved in 70% solution A (acetonitrile: H_2O 60:40, 10 mM ammonium formate and 0.1% formic acid) and 30%

solution B (isopropanol:acetonitrile 90:10, 10 mM ammonium formate and 0.1% formic acid). The lipids were loaded onto a C18 column (Acclaim PepMap 100, C18, 75 $\mu\text{m} \times 15\text{ cm}$, Thermo Scientific) by a Dionex UltiMate 3000 RSLC Nano system coupled to an LTQ Orbitrap XL hybrid mass spectrometer (Thermo Fisher Scientific). The lipids were separated with a gradient from 30 % buffer B to 99 % buffer B. The LTQ-Orbitrap XL was set up in negative ion mode and in data-dependent acquisition mode to perform five MS/MS scans per MS scan. Survey full-scan MS spectra were acquired on the Orbitrap (m/z 400–2,000) with a resolution of 60,000. Collision-induced dissociation (CID) fragmentation in the linear ion trap was performed for the five most intense ions. Lipid analysis was replicated three times.

Statistical analysis: Liposomal flux assay

Each liposomal flux experiment was performed across at least three independent reconstitution experiments. Each independent measurement was the result of averaging between two and six technical replicates. To assess significance, a two-sided Dunnett's multiple comparisons test was carried out to compare each experimental condition to either channel-free liposomes or wild type-KirBac3.1 proteoliposomes. Significance was determined by a family-wide threshold of 0.05, with the P-value for each comparison adjusted for multiplicity. For each experimental condition, the number of independent (and constitutive technical) replicates and P-values as determined by the Dunnett's multiple comparisons are summarised in [Supplementary Tables 3 and 4](#).

Statistical analysis: Crystallography

Crystallographic statistics are provided in [Supplementary Table 1](#).

Data availability

Atomic coordinates and structure factors have been deposited in the Protein Data Bank with accession codes 7N9L and 7N9K. All data is available upon request from the authors.
