48 **Abstract**

49 Extinctions stemming from environmental change often trigger trophic cascades and
50 coextinctions. However, it remains unclear whether trophic cascades were a large contributor
51 to the megafauna extinctions that swept across several continents in the Late Pleistocene. The
52 pathways to megafauna extinctions are particularly unclear for Sahul (landmass comprising
53 Australia and New Guinea), where extinctions happened earlier than on other continents. We
54 investigated the role of bottom-up trophic cascades in Late Pleistocene Sahul by constructing
55 pre-extinction (~ 80 ka) trophic network models of the vertebrate community of Naracoorte,
56 south-eastern Australia. These models allowed us to predict vertebrate species' vulnerability
57 to cascading extinctions based on their position in the network. We tested whether the
58 observed extinctions could be explained by bottom-up cascades, or if they should be
59 attributed to other external causes. Species that disappeared from the community were more
60 vulnerable, overall, to bottom-up cascades than were species that survived. The position of
61 extinct species in the network – having few or no predators – also suggests they might have
62 been particularly vulnerable to a new predator. These results provide quantitative evidence
63 that trophic cascades and naivety to predators could have contributed to the megafauna
64 extinction event in Sahul.

66 **Introduction**

67 Of all the extinctions that have ever occurred on Earth, many — potentially most — have
68 been coextinctions [1]. In some cases, these coextinctions involved host-specific parasites
69 that were doomed by the extinction of their host species, or flowering plants imperilled by the
70 extinction of their pollinators [2]. Coextinctions have also been mediated through trophic
71 interactions between herbivores and vegetation, and between predators and their prey [3,4].
72 Therefore, if we are to understand past extinction events and predict future extinctions, we
73 need to be able to infer coextinction cascades accurately.

74 Changes in the primary producer component of a community can trigger bottom-up
75 cascades and profoundly alter ecological communities [5]. However, it is unclear which
76 species are most vulnerable to bottom-up cascades. On the one hand, it has been argued that
77 top predators and species from high trophic levels are particularly sensitive to food-web
78 perturbations and reductions in habitat area/primary productivity [6–9]. However, others have
79 concluded that changes in the diversity of primary producers or nutrient content most
80 strongly affect herbivores, and the cascading effects on higher trophic levels are dampened by

81 trophic distance [10–13]. Similarly, extinction-risk assessments by the International Union
82 for Conservation of Nature (IUCN) and recorded recent extinctions suggest that herbivorous
83 terrestrial vertebrates are particularly vulnerable to extinction [14], a pattern that might partly
84 be explained by the sensitivity of lower trophic levels to bottom-up cascades. The uncertainty
85 regarding how vulnerability to bottom-up cascades varies with species traits (such as trophic
86 level) has limited our ability to assess the importance of bottom-up cascades in past
87 extinction events, and to predict how these cascades might unfold in the future.

88 Identifying the vulnerability of species to bottom-up (or top-down) coextinction cascades
89 relies heavily on understanding species interactions within an ecological community. To this
90 end, ecological network modelling is an invaluable tool for representing ecological
91 communities from the perspectives of species interactions and for studying the consequences
92 of changes in these interactions [15]. In ecological network models, organismal groups (e.g.,
93 species, age groups, populations, or individuals) are represented by nodes, and interactions —
94 which can be weighted or unweighted — are represented by links (edges). The interaction
95 type most frequently used to build ecological network models are trophic interactions (i.e.,
96 food webs). For contemporary communities, there is a growing number of studies that use
97 detailed information on species interactions to build network models and to study trophic
98 cascades [16–18]. Unfortunately, similar approaches are challenging to apply to palaeo-
99 communities because of the lack of data on ancient trophic interactions. However, by
100 combining contemporary and palaeo-data to infer trophic interactions, this limitation can be
101 overcome and network models of palaeo-communities can be constructed [19,20]. For
102 example, Pires et al. (2015) used this approach to model Late Pleistocene mammal
103 communities in the Americas, concluding that (1) pre-existing American mammal networks
104 were not especially unstable (i.e., they were similar to modern networks in Africa in terms of
105 population densities re-establishing after simulated perturbations), and (2) the arrival of
106 humans destabilized the networks because this new predator increased network connectance
107 (i.e., the proportion of potential links that are realized). Investigations of paleo mass
108 extinctions are fortified through the use of network modelling, as these methods provide
109 insights into the causes and consequences of extinction events. Such events can also be used
110 as a means of validating modelling methods because the outcomes (i.e., extinctions) are
111 known. Despite these opportunities, the application of network modelling to investigate
112 palaeo-extinction events remains under-utilised.

113 Megafauna (animals > 44 kg) extinctions swept across several continents during the Late
114 Pleistocene (126,000 – 12,000 years ago), with the highest proportions of genera lost from

115 Sahul (landmass including Australia and New Guinea) and the Americas [21,22]. While the
116 causes of these extinctions are still debated, most evidence points toward the arrival of
117 anatomically modern humans and/or climate change [23–25]. Irrespective of the root causes,
118 large extinction events such as these always involve both primary and secondary (or co-)
119 extinctions [3]. Indeed, it has been argued that the loss of prey species led to large predators
120 going extinct in the Late Pleistocene [26,27]. Although the arrival of modern humans and/or
121 climate change have been identified as the most likely ultimate causes of megafauna
122 extinctions in the Late Pleistocene, vegetation change associated with human arrival and/or
123 climate change has been identified as a pathway through which these ultimate causes could
124 have triggered extinctions (i.e., via bottom-up trophic cascades) [28–31].

125 The Late Pleistocene megafauna assemblage of Sahul was distinct from that of other
126 continents in that all the large mammals were marsupials or monotremes [32]. Giant reptiles
127 and birds were also a prominent component of the continent’s megafauna [33]. While Sahul’s
128 megafauna included many species over the standard body-mass threshold of 44 kg, the term
129 ‘megafauna’ is often extended to include species with a body mass above that of their
130 surviving relatives [32] — a definition we have adopted here. Identifying the pathways by
131 which Sahul’s unique megafauna were lost is challenging because their extinctions happened
132 much earlier in Sahul than elsewhere [34]. To characterize such ancient extinction events, a
133 sufficient number of dated fossilized remains is necessary [35]. The most detailed and well-
134 studied fossil record spanning the megafauna extinction event in Sahul comes from the
135 Naracoorte region in south-eastern Australia (Figure 1). This fossil record offers an
136 exceptional picture of the species living in the region over the past 500,000 years, including
137 the ecological community at the time of the main megafauna extinction event that occurred
138 approximately 44,000 years ago in Naracoorte [25]. Thus, the Naracoorte fossil record is the
139 best platform available from which to model the ecological and environmental processes
140 potentially involved in megafauna extinctions in Sahul.

141 We assessed how vulnerability to bottom-up cascades varies with network-position
142 attributes and whether bottom-up coextinction cascades stemming from the loss of basal
143 resources (i.e., primary producers/plants) could have played a role in the megafauna
144 extinctions of Sahul. First, we built small, synthetic networks (3 to 20 nodes) varying in
145 topology (i.e., structure of connections), and calculated each node’s coextinction vulnerability
146 using two methods: (i) simulation, and (ii) Bayesian networks. This allowed us to test the
147 general influence of trophic level, diet breadth, and number of connected basal resources on
148 vulnerability to bottom-up coextinction cascades.

149 Next, we used Naracoorte as a model system to assess whether bottom-up coextinction
150 cascades could explain which species went extinct during the Late Pleistocene event. We
151 constructed an entire terrestrial, palaeo-vertebrate assemblage (including all terrestrial
152 vertebrate classes), and combined this assemblage with palaeo and contemporary data to infer
153 trophic interactions and build network models (Figure 2). These network models consisted of
154 nodes (species) with directed, unweighted links. We then computed each species'
155 vulnerability to coextinction via bottom-up cascades using the simulation method we
156 validated with the synthetic networks, and we compared the coextinction vulnerabilities (and
157 the traits influencing them) between extinct and extant (surviving into the Holocene) species.
158 In addition to vulnerability to bottom-up coextinction cascades, we also tested for differences
159 in the network positions of extant and extinct species to determine if relative position could
160 have made extinct species more vulnerable in other ways (e.g., more vulnerable to a new
161 predator). By incorporating interactions involving all vertebrate species, we adopted a holistic
162 approach to studying megafauna extinctions of the Late Pleistocene.

163 We found that vulnerability to bottom-up cascades decreases with increasing trophic
164 level, diet breadth, and basal connections, and that extinct species were more vulnerable to
165 bottom-up coextinction cascades than were extant species. This suggests that bottom-up
166 trophic cascades possibly contributed to the megafauna extinction event in Sahul. Our results
167 also indicate that extinct species had fewer predators than did surviving species, suggesting
168 that extinct species might have been particularly sensitive to the arrival of the new predator
169 *Homo sapiens*.

170

171 **Methods**

172 We aimed to: (1) identify how vulnerability to bottom-up cascades varies with trophic level,
173 diet breadth, and basal connections using synthetic networks, and (2) develop and interrogate
174 ecological network models representing the Naracoorte ecosystem prior to the main
175 megafauna-extinction pulse and the arrival of humans in the region (~ 44,000 years ago) [25].
176 Below, we describe how we generated the synthetic networks, measured node vulnerability to
177 bottom-up cascades, built ecologically realistic models of the Naracoorte network, and tested
178 whether bottom-up coextinction cascades could explain which species were lost from the
179 Naracoorte network (see Supplementary Figure S1 for a flowchart of methods for the
180 construction and analysis of the Naracoorte network).

181

182 *Synthetic networks*

183 We randomly generated 196 ‘synthetic’ networks that differed in topology. The networks
184 varied in size (number of nodes: 3 to 20), number of links (2 to 92), and connectance (0.07 to
185 0.33). Within these networks, nodes varied in trophic level (1 to 4), number of ‘in’ links (1 to
186 8), and the number of basal nodes to which non-basal nodes were directly or indirectly
187 connected through ‘in’ links (1 to 8). We generated these networks to test how a node’s
188 vulnerability to the removal/extinction of basal nodes (analogous to plants/primary
189 producers) varied depending on the node’s trophic level, diet breadth (number of ‘in’ links),
190 and the number of basal resources to which it was connected.

191

192 *Coextinction vulnerability in synthetic networks*

193 We inferred vulnerability of nodes to bottom-up cascades via: (i) simulations, and (ii) a
194 Bayesian network method [36]. We applied two different approaches because there is
195 uncertainty regarding the best methods to infer vulnerability to bottom-up cascades [3], so
196 consensus using both approaches would provide more robust results than relying on only one.
197 In the simulation method, primary extinctions occur by randomly removing basal nodes from
198 the network, after which coextinctions are simulated by removing nodes that had lost all their
199 ‘in’ links. Based on 1000 iterations of each network, we calculated the average coextinction
200 vulnerability of each node as the proportion of total basal resources remaining when
201 coextinction occurred. Applying the Bayesian-network method to the same networks [36],
202 baseline extinction probabilities are assigned to each node and then each node’s accumulative
203 extinction vulnerability is calculated using the network structure (taking into account each
204 node’s dependencies on other nodes). In our case, we adjusted baseline probabilities of
205 extinction so that primary extinctions were restricted to basal nodes.

206

207 *Analysis of synthetic networks*

208 We fit mixed-effects models to the results from the simulation and Bayesian network
209 approaches to assess if the two methods yielded similar results in terms of the effects of
210 trophic level, diet breadth, and basal connections on vulnerability to bottom-up coextinction
211 cascades. Prior to fitting, we scaled the independent variables so that the units of the
212 regression coefficients were the same for all variables. The full/global mixed-effects model
213 had coextinction vulnerability as the dependent variable (response), trophic level, diet
214 breadth, number of connected basal nodes, and the interactions between these traits as
215 independent variables (fixed effects), and network identity as a random effect. We compared

216 support for the full models with every combination of nested/reduced model using Akaike's
217 information criterion weights ($wAIC_c$). If including trophic level, diet breadth, and number of
218 basal connections resulted in models with higher $wAIC_c$, this suggests these variables affect
219 vulnerability. We calculated model-averaged (via $wAIC_c$) coefficients for the independent
220 variables to identify how each variable influenced vulnerability. We also extracted marginal
221 R^2 from three mixed effects models that had either trophic level, diet breadth, or basal
222 connections as the only independent variable to estimate how much variation in vulnerability
223 each of these variables explained.

224

225 *Naracoorte study region*

226 The World Heritage-listed (from 1994) Naracoorte Caves in south-eastern South Australia
227 (37° 02' 24" S, 140° 48' 00" E) encompass a series of limestone caves that opened and closed
228 to the surface at different locations, and at different times, over the last 500,000 years [37].
229 These openings acted as natural pitfall traps, capturing snapshots of Naracoorte's biodiversity
230 at different periods from at least 500,000 years ago to the present. In addition to the fossils of
231 the many animals that fell into these natural traps, there are remains of species that lived in
232 the caves, such as owls and bats, and their prey [38]. Consequently, the Naracoorte Caves
233 provide an ideal platform from which to build palaeo-ecological network models to gain
234 insight into how these long-lost ecosystems functioned and changed over time.

235

236 *Species data*

237 To build a species assemblage list (i.e., to identify the nodes to include in the network
238 models), we used two data sources: *FosSahul* 2.0 [35,39] and the Atlas of Living Australia.
239 *FosSahul* 2.0 is a database of dated fossil records from Sahul, including an automated
240 quality-rating method for date reliability [40]. We extracted and vetted records from the
241 Naracoorte region (defined as the region between 35° 32' 48" S and 38° 6' 50" S, and
242 between 139° 10' 42" E and 141° 0' 21" E) from *FosSahul* 2.0 that had high- or intermediate-
243 quality dates (A*, A or B) [35], and whose age was younger than 200,000 years before
244 present. We chose this cut-off age to provide a large enough period to include dated fossils
245 from all/most megafauna species that lived in the region immediately prior to the main
246 extinction event; if we had made the period too narrow, few megafauna species would have
247 been captured despite their likely presence in the region at the time. Fossil records suffer
248 from taphonomic biases (biases in the accumulation and preservation of different organisms),
249 and, consequently, some species that were present in Late Pleistocene Naracoorte are unlikely

250 to be represented in the fossil record. Furthermore, there are biases for studying and dating
251 particular groups of species due to academic and amateur interests [41]. These biases, along
252 with the fact that *FosSahul* was primarily designed to document megafauna remains rather
253 than smaller species, means that *FosSahul 2.0* does not include all vertebrate species present
254 in Late Pleistocene Naracoorte. To account for this gap in the species list, we supplemented
255 *FosSahul 2.0* data with contemporary and historical species records from the Naracoorte
256 Coastal Plains bioregion from the Atlas of Living Australia online repository (ala.org.au;
257 accessed 3 January 2019). The Atlas of Living Australia has detailed species records of
258 vertebrates from this bioregion, and so it captures most of the diversity of extant and recently
259 extinct vertebrate species. We extracted data pertaining to all terrestrial vertebrates from the
260 region, and removed species that were introduced since European arrival, as well as vagrants
261 and erroneous records (species well-outside their normal distribution and not present in the
262 fossil record), and strictly coastal species such as marine birds that do not use inland
263 waterways. Our final species list, built using *FosSahul 2.0* and the Atlas of Living Australia,
264 included 280 birds, 81 mammals, 50 reptiles, and 12 amphibians (Supplementary Table S1).

265 The fossil record and phylogeography of extant mammal species (i.e., the vertebrate class
266 most intensively studied) from the Naracoorte region suggest that, at a fine spatial scale, the
267 distributions of some species expanded and contracted with climatic fluctuations during the
268 Late Pleistocene and Holocene, but that during times of contraction species persisted at a
269 regional scale (as in our study) in refugia [42–44]. Furthermore, most extant mammals
270 recorded in the Late Pleistocene fossil record at Naracoorte were present (living) in the
271 Naracoorte bioregion when Europeans arrived, suggesting little species turnover (apart from
272 megafauna) between the Late Pleistocene and European arrival [42–44]. Together, these
273 results suggest that our approach of using the fossil record and modern presence data
274 provides a reasonable estimate of the species likely present in the region in the Late
275 Pleistocene.

276 To infer trophic links, we required information on each species' body mass and broad
277 trophic category (whether it ate plants and/or fungi, invertebrates, terrestrial vertebrates, or
278 fish). For extant species, we extracted much of this information from large databases: snake
279 database [45]; Australian bird database [46]; *PanTHERIA* (mammal database) [47]; lizard
280 database [48]; *AmphiBIO* (amphibian database) [49]; tropical bird database [50]; Amphibian
281 database [51]; reptile database [52]; and Elton traits databases (mammals and birds) [53].
282 However, information on body mass was not available for some extant reptiles and
283 amphibians. For these species, we estimated body mass using their body length (from field

284 guides) and validated allometric relationships [45,48,51,54,55]. Extinct megafaunal species
285 were not included in any of the aforementioned databases, so for these species we obtained
286 body mass and diet data from the literature (see Supplementary Table S2). The 423 vertebrate
287 species in the Naracoorte assemblage included 125 that consumed vertebrates, 249 that
288 consumed plants, 362 that consumed invertebrates, and 48 that consumed fish
289 (Supplementary Table S1). Of the 423 species, 273 consumed more than one of these
290 resource groups. Mean species body mass ranged from 0.4 g to 2700 kg (Supplementary
291 Table S1).

292

293 *Inferring trophic links*

294 For almost all extant species, information on trophic interactions is incomplete, but the lack
295 of knowledge regarding trophic interactions is even greater for long-extinct species. To
296 overcome this limitation and build realistic ecological network models, various methods have
297 been developed for inferring trophic links using species' traits such as body size (i.e., larger
298 predators tend to eat larger prey, and predators are usually bigger than their prey) [56]. Others
299 have built on this approach to improve prediction accuracy [57–60] by adding phylogenetic
300 and physiological information, prohibiting impossible or unlikely links, incorporating
301 specific morphological features such as biting force and cuticular thickness, and taking into
302 account abundance. However, most of this research focusses on fish or invertebrates, with the
303 effectiveness of these methods rarely applied or validated for terrestrial vertebrates, but see
304 [61,62].

305 We therefore developed and validated a new method, based on the body-size trophic-niche
306 model [56], to infer trophic links between terrestrial vertebrates. The body-size trophic-niche
307 model that we adapted consists of two quantile regressions: (i) one defining the upper prey-
308 size limit given predator mass, and (ii) the other defining the lower prey-size limit given
309 predator mass. If a species falls within the upper and lower limits for a particular predator, it
310 is inferred as potential prey for that predator. We used a large predator-prey interaction
311 dataset to identify these body-size relationships between terrestrial predators and their prey,
312 and tested whether these relationships varied depending on the predator's taxonomic class
313 (i.e., did including predator class as an independent variable improve the fit of the body size
314 quantile regressions?).

315 We extracted the interaction dataset from *GloBI*, an online repository of biotic interactions
316 [63]. The dataset consisted of 3893 records: 958 records of predation by non-marine
317 mammals, 2711 by birds, 199 by reptiles, and 25 by amphibians (Supplementary Table S3)

318 [64]. We extracted data on mean body mass for the species from the same databases we used
319 to add this information to the Naracoorte species list (see above). Once we identified the best
320 trophic-niche model (i.e., the combination of quantile regressions that best fit the upper and
321 lower prey-size limits) using the entire *GloBI* dataset and Bayesian information criterion
322 (BIC; Supplementary Methods S1), we validated this method of assigning trophic links by
323 comparing model performance when applied first to the *GloBI* data divided into training and
324 validation datasets, and then to a well-resolved trophic network from the Serengeti [65] (see
325 also S. de Visser unpublished data; Supplementary Methods S1). We used the true skill
326 statistic to evaluate model performance and found that the top-ranked model (according to
327 BIC) also performed best at assigning links in the validation step (Supplementary Methods
328 S1, Supplementary Table S4, Supplementary Figure S2, script available at [64]). We used the
329 best trophic-niche model to identify potential prey for each predator of vertebrates (see
330 methods below; Supplementary Methods S1; script available [64]).

331 While including additional species traits could improve the accuracy of inferred predator-
332 prey interactions, we used only three readily available traits (broad diet, body size, and
333 predator taxonomic class — with reptiles and amphibians grouped together). We used only
334 these three traits because: (1) using few traits is compatible with the quantile regression
335 framework, (2) they can easily be extracted for vertebrate species in most assemblages (and
336 therefore the method can be widely applied), and (3) our validation steps demonstrated the
337 resulting performance of the trophic-niche model is sufficient (true skill statistic [TSS] = 0.6
338 when applied to the Serengeti assemblage; TSS varies from -1 to 1, with a score of 0
339 indicating no better than random; Supplementary Table S5).

340

341 *Naracoorte networks*

342 To build realistic ecological networks for the Naracoorte assemblage, we applied the trophic-
343 niche model to the species list, removed excess links between vertebrates (to account for
344 overestimating the number of predator-prey links), and added links to non-terrestrial
345 vertebrate food resources. However, there is uncertainty regarding which vertebrate
346 predator/prey links to delete as well as how many links to add from non-terrestrial vertebrate
347 food resources to vertebrates. To address this uncertainty, we used a randomization approach
348 in the link-removal and -addition steps described below, and generated 1000 versions of the
349 network. That is, we randomly removed (for the vertebrate predator-prey links) or added (for
350 the herbivores, invertivores, and piscivores) links in the range indicated as realistic based on
351 contemporary species' diet breadths. Because we do not know exactly where to add or

352 remove these links, we generated 1000 versions of the network so our results were not
353 skewed by the particular links selected.

354 We used the trophic-niche model to assign potential predator-prey links in the Naracoorte
355 species assemblage. Although trophic-niche models are good at identifying potential links,
356 they almost always overestimate the number of realized links [66]. This is because predators
357 are unlikely to consume all prey within their size range — some species are not palatable, are
358 dangerous, too rare, difficult to capture, use different microhabitats, or have other ecological
359 characteristics that make them unsuitable for regular consumption [66]. To build a network
360 with a more realistic structure, we assigned a probability to each interaction based on the
361 prey's position in the predator's prey-size range and a Gaussian distribution centred on this
362 range (with a standard deviation equal to one quarter of the predator's prey-size range); the
363 highest probability was for prey close to the centre of the prey-size range (i.e., centre of the
364 distribution) and decreased the closer the prey was to the predator's limits. For each predator,
365 we randomly sampled from a density kernel fit to published carnivore diet breadths ($n = 12$;
366 sampled between 1 and twice the maximum diet breadth in Supplementary Table S6a;
367 Supplementary Methods S1) to select the number of potential prey that were 'realized' prey.
368 In assigning the sampled diet breadths to individual predators, predators with more potential
369 prey (indicated by the trophic-niche model) were assigned larger diet breadths than were
370 those with fewer potential prey. To account for different degrees of dietary specialisation, we
371 Poisson-resampled the number of potential prey for each predator before ranking predators
372 according to their number of potential prey, slightly shuffling relative diet breadths between
373 network models. Then, using the assigned diet breadths, we randomly selected from the
374 potential prey, taking into account the probability of the predator-prey interaction. This
375 method resulted in a vertebrate network with realistic connectance (proportion of potential
376 links that are realized), and with most of each predator's prey closer to the centre, rather than
377 the limits, of their prey-size range.

378 Terrestrial vertebrates not only consume other terrestrial vertebrates, they also consume
379 invertebrates, plants, fungi, and fish. In addition to inferring trophic links among terrestrial
380 vertebrates, we therefore needed to add links to vertebrates from these other food resources.
381 However, we did not include detail on individual species within these resource groups
382 because: (i) our study focusses on terrestrial vertebrate species; (ii) invertebrate, plant, and
383 fungal diversities are not well resolved for most ecosystems (including for Late Pleistocene
384 Naracoorte); and (iii) fish only constitute a small part of the Naracoorte community in terms
385 of biodiversity and biomass. We therefore generated a pool of n species for each of these

386 groups ($n = 1300$ for plants, 6000 for invertebrates, and 23 for freshwater fish), with the
387 number of invertebrate and plant species calculated based on the described diversity in these
388 groups relative to terrestrial vertebrate diversity in Australia [67], and the number of fish
389 determined by the diversity of freshwater fish recorded in the Naracoorte Coastal Plains
390 bioregion in Atlas of Living Australia (ala.org.au; accessed 6 April 2021). To assign links to
391 vertebrates from species in these groups, we used published records of vertebrate diet breadth
392 for 20 herbivores, 6 invertivores, and 9 piscivores (Supplementary Tables S6a and 6b). We fit
393 kernel densities to the invertivore, herbivore, and piscivore diet breadth data, and randomly
394 sampled (within a diet breadth range of 1 to twice the maximum diet breadth recorded for that
395 trophic guild in Supplementary Table S6a and S6b) from these distributions to assign the
396 number of links between each resource group and vertebrate consumer in each of the 1000
397 network models. However, because the published piscivore diet breadths (Supplementary
398 Table S6b) came from terrestrial Australian predators that are not exclusively piscivorous, we
399 multiplied the number of fish in the diets of these predators by the number of resource groups
400 from which the predator fed before fitting and sampling from the kernel densities. This
401 modification was made to offset the adjustment accounting for inflated diet breadths in
402 omnivores (described below).

403 For vertebrates that fed from more than one group (i.e., omnivores, which represent over
404 half the vertebrates in this network), we proportionally adjusted the number of ‘in’ links
405 (food resources) depending on how many food groups they fed. For example, if a
406 species consumed from two groups (e.g., vertebrates and invertebrates), we randomly deleted
407 half of the links from each group; if they fed from three groups, we randomly removed two-
408 thirds of the links from each food group (and so on). We made these deletions to prevent
409 omnivores from having inflated diet breadths.

410 In some cases involving water birds, we used empirical evidence to avoid assigning
411 unrealistic trophic links. For example, pelicans are large and, consequently, the trophic-niche
412 model predicts that pelicans take large vertebrate prey. However, we know that pelicans are
413 not birds of prey and do not consume large terrestrial animals. Thus, we restricted the
414 allocation of trophic links for such birds to prevent them from feeding on unrealistically large
415 terrestrial vertebrates (they were prevented from consuming prey that weighed over a third of
416 their body mass).

417 We completed the networks by generating links from plants to invertebrates and from
418 plants to fish. To determine diet breadth for these herbivores, we sampled from a Pareto

419 distribution ($\alpha = 1.02$, truncated at 52) following ref [68]. The α and truncation
420 values were based on a temperate woodland system (i.e., similar to Naracoorte) [68–70].

421

422 *Analysis of Naracoorte models*

423 We estimated the coextinction vulnerability of Naracoorte vertebrates using the same
424 simulation approach as we applied to the synthetic networks i.e., plant nodes were iteratively
425 (and randomly) removed to simulate primary extinctions, and coextinctions were triggered
426 when animals lost all their food resources. We measured each species' coextinction
427 vulnerability as the proportion of plant nodes remaining when coextinction occurred. We
428 repeated the simulations 1000 times for each of the 1000 network models to test whether: (1)
429 the effects of trophic level, diet breadth, and basal connections (direct and indirect) on
430 coextinction vulnerability were consistent with results obtained from the synthetic models,
431 and (2) vulnerability to bottom-up cascades differed between extinct and extant species.

432 To test whether the coextinction vulnerability results were consistent with those from the
433 synthetic models, we fit linear-regression models to the data with vulnerability to
434 coextinction cascades as the response, and trophic level, diet breadth, basal connections, and
435 the interactions between these variables as independent variables (fixed effects). Rather than
436 using the raw data from the 1000 network models, we used each species mean value for each
437 trait and vulnerability for these analyses. We then compared relative model probabilities
438 ($wAIC_c$) for the full model to all possible reduced models, and examined the coefficients of
439 the main effects to determine if they were similar to those obtained from the synthetic
440 networks.

441 We compared susceptibility of Naracoorte's extinct *versus* extant species to bottom-up
442 coextinction cascades in three steps. First, we compared the groups in terms of their trophic
443 level, diet breadth, and number of basal connections to determine if differences in these
444 variables suggest one group would be more vulnerable than the other. Second, to test for an
445 association between coextinction vulnerability and extinction status, we compared $wAIC_c$
446 support for two models: a null model with vulnerability to coextinction as the dependent
447 variable and no fixed effects *versus* a model that was identical to the first model, except with
448 extinction status as an independent variable. Third, we ran a randomization test to assess the
449 probability that extinct species were more vulnerable to coextinction than were extant
450 species. Here, we sampled the coextinction vulnerabilities of 10 extinct and 10 extant species
451 from each of the 1000 models 20 times (i.e., using the raw data rather than species means),

452 and each time calculated the mean difference in coextinction vulnerability between the two
453 groups.

454 We also assessed the position of extinct *versus* extant species in the network using 12
455 different network metrics: *trophic level*, *pageRank*, *betweenness centrality*, *eigenvector*
456 *centrality*, *closeness centrality (in)*, *coreness (in)*, *degree (in)*, *eccentricity (in)*, *closeness*
457 *centrality (out)*, *coreness (out)*, *degree (out)*, and *eccentricity (out)* (Supplementary Table S7
458 for metric descriptions). We calculated the metrics followed by an ‘in’ or ‘out’ for each node
459 using links pointing towards (in) or away from (out) the focal node. We chose these metrics
460 because they are commonly used, node-level metrics describing position in the network. For
461 each metric, we calculated the species’ mean value across the 1000 network models. After
462 checking for highly correlated metrics and removing those identified as redundant (i.e.,
463 metrics that had a Spearman’s $\rho > 0.8$), we ran a principal component analysis and visually
464 inspected for grouping of extinct and extant species. The reduced list of metrics included
465 *closeness centrality (out)*, *eccentricity (out)*, *degree (in)*, *coreness (in)*, *betweenness*, and
466 *PageRank*.

467

468 **Results**

469 *Synthetic networks*

470 The two methods calculating bottom-up coextinction vulnerability (simulation and Bayesian
471 network) yielded similar results in terms of the effects of trophic level, diet breadth, and basal
472 connections on node vulnerability to bottom-up coextinction cascades. $wAIC_c$ indicated that
473 the full models (i.e., that had all three independent variables and their interactions) were more
474 strongly supported than reduced models using both approaches, with the full models having
475 $wAIC_c > 0.999$ (Supplementary Tables S8 and S9). The weighted model-averaged
476 coefficients describing the relationships between the three independent variables and
477 coextinction vulnerability were negative, irrespective of which of the two methods we used to
478 calculate vulnerability (Figure 3A; Supplementary Tables S8 and S9). These negative
479 correlations indicate that vulnerability to bottom-up cascades decreased with increasing
480 number of basal connections, diet breadth, and trophic level. Marginal R^2 of the three reduced
481 models, each of which had one of the three variables as a main effect, suggest that the
482 number of basal connections explained most of the variation in coextinction vulnerability in
483 the synthetic networks (Figure 3B). We restricted our analyses of the Naracoorte network
484 models to the simulation method because both approaches yielded similar results, and

485 because the Bayesian network method was prohibitively time consuming for networks of the
486 size of the Naracoorte models.

487

488 *Naracoorte network*

489 In terms of the effects of trophic level, diet breadth, and basal connections on vulnerability,
490 the patterns in the Naracoorte network were similar to those from the synthetic networks
491 (Supplementary Table S10). $wAIC_c$ strongly supported the full model over reduced models
492 ($wAIC_c \approx 1$ for the full model; Supplementary Table S10), and the three main effects were
493 negatively correlated with coextinction vulnerability (Figure 4A; Supplementary Table S10).
494 Reduced models that had either trophic level, diet breadth, or basal connections as the only
495 independent variable had $R^2 > 0.23$, indicating that each of these variables were associated
496 with a substantial proportion of variation in vulnerability (Figure 4B).

497 Extinct species had fewer basal connections, narrower diet breadths, and came from lower
498 trophic levels, on average, than those species that survived into the Holocene (Figure 5A-C;
499 mean basal connections: 298 vs. 515; diet breadth: 34 vs. 79; and trophic level: 2.3 vs. 2.9 for
500 extinct *versus* extant species). Extinct species also had higher coextinction vulnerability than
501 did surviving species (Figure 5D; mean coextinction vulnerability \pm 95% confidence interval:
502 0.045 ± 0.015 vs. 0.008 ± 0.002 for extinct and extant species, respectively), a result
503 consistent with coextinction vulnerability being higher for species with fewer basal
504 connections, narrower diet breadth, and from lower trophic levels.

505 To test for an association between species' extinction status and vulnerability to bottom-up
506 cascades, we compared support for a model with coextinction vulnerability as the dependent
507 variable and extinction status as the only fixed effect *versus* a null model (a random-intercept
508 model with no fixed effects), and we also did a randomization test comparing the
509 coextinction vulnerability of extinct *versus* extant species. Both approaches indicated that
510 extinction status was associated with vulnerability to bottom-up cascades, with extinct
511 species more vulnerable than those that survived into the Holocene. The $wAIC_c$ for the model
512 with extinction status as a fixed effect was ~ 1 , indicating that this model was strongly
513 supported over the null model. The randomization test showed that extinct species had a
514 probability of 0.91 of being more vulnerable to bottom-up coextinctions than extant species
515 (Figure 6).

516 Extinct species differed from extant species in terms of their position in the network.
517 Principal component analysis of six network-position metrics showed that extinct and extant
518 species fell into two distinct groups according to the second principal component (dimension

519 2 in Figure 7A). The main contributors to this principal component are metrics describing a
520 node's connection to the network through its 'out' links, including the closeness centrality
521 (out) and eccentricity (out) metrics (Figure 7A; Supplementary Figures S3 and S4). Closer
522 examination of the out links (i.e., number of predators) showed that, on average, extinct
523 species had < 1 predator, whereas extant species had > 3 (Figure 7B; mean number of
524 predators: 0.2 vs. 3.3 for extinct vs. extant species). Indeed, the average number of predators
525 was lower for extinct than extant species in all 1000 models of the Naracoorte network.

526

527 **Discussion**

528 Our analyses demonstrate that a species' vulnerability to bottom-up coextinction cascades
529 varies depending on its trophic level, diet breadth, and number of basal connections. We also
530 found that the position of extinct species in the Naracoorte network — being primarily
531 herbivorous (low trophic level), and therefore having relatively narrow diet breadths and few
532 pathways to basal resources — might have made them more vulnerable to bottom-up
533 coextinction cascades than were co-occurring species that survived into the Holocene. The
534 Naracoorte results suggest that trophic cascades potentially contributed to the megafauna
535 extinction event in south-eastern Sahul. However, the extinct species from Naracoorte also
536 had fewer predators than did extant species, a network position attribute that would likely
537 have made them more vulnerable to the arrival of the new 'super predator' — humans [71].

538 The Naracoorte and synthetic network models revealed that vulnerability to bottom-up
539 coextinction cascades precipitated by plant extinctions decreased with increasing trophic
540 level, diet breadth, and number of basal connections (Figures 3 and 4; Supplementary Tables
541 S8, S9 and S10). Our results therefore support previous findings that species with narrower
542 diet breadths/fewer pathways to basal resources are more vulnerable to bottom-up
543 coextinction cascades [72–74]. However, previous research does not provide a clear
544 expectation regarding the relationship between trophic level and extinction vulnerability. It is
545 often assumed that higher trophic levels are more vulnerable to extinction than are lower
546 levels due to the cumulative effects of disturbances on lower trophic levels (on which higher
547 trophic levels depend), and direct persecution by humans [8,9]. However, our analyses that
548 specifically tested for sensitivity of species to primary extinctions in the plant community
549 imply that vulnerability to these bottom-up cascades in fact *decreases* with trophic level.
550 Consistent with these results, several manipulative experiments of ecological communities

551 have revealed that changes in the plant component of the community most strongly affect
552 herbivores, and impacts on higher trophic levels diminish with trophic distance [10,13,75].

553 This pattern has also been identified in theoretical studies. Applying Rosenzweig–
554 MacArthur models and synthetic (but ecologically feasible) networks, the loss of primary
555 producers triggered extinctions in herbivores before doing so in carnivores, and herbivores
556 were more vulnerable to these cascades than were carnivores [74]. However, our
557 vulnerability scores were based on coextinction being triggered when a consumer lost all
558 food resources. Coextinctions could be triggered at lower thresholds and/or vary between
559 species. While the congruence between our results and those from previous studies support
560 the methods and threshold we used, further investigation into how coextinction threshold
561 influences the effect of network position on node vulnerability, as well as how coextinction
562 thresholds covary with species/community traits, is needed to refine methods for predicting
563 the probability and magnitude of bottom-up cascades.

564 The extinction pattern observed in the Naracoorte assemblage could have been the result
565 of bottom-up cascades triggered by changes in the plant community, as demonstrated by our
566 vulnerability modelling. This leads to the question: did vegetation change at the same time as
567 the megafauna disappeared? Studies in other regions of Sahul have detected shifts in
568 vegetation roughly coinciding with, or immediately preceding, megafauna extinction.
569 Hypothesised drivers of these vegetation shifts include land-use changes associated with
570 human arrival (i.e., fire-stick farming) [28,76] and/or climate change [77]. However, there are
571 no detailed studies on the vegetation of Naracoorte spanning the Late Pleistocene extinction
572 event (but see [78] for a review of broad proxies of vegetative change over this period). The
573 megafauna's disappearance from Naracoorte did, nonetheless, coincide with an unusually
574 cool period (Supplementary Figure S5) and the arrival of humans (~ 44,000 years ago) [25],
575 offering the intriguing possibility that changes in climate and/or land use triggered shifts in
576 vegetation that had consequences for higher trophic levels in the network. To evaluate this
577 possibility, more studies are required to model vegetation changes in south-eastern Sahul
578 (including the Naracoorte region), and these must be validated using the pollen record and/or
579 other fossil data.

580 By considering the network position of all vertebrate species in the assemblage, a clear
581 difference between extinct and extant species emerged — extinct species had fewer predators
582 than did species that survived (mean number of predators: 0.2 *versus* 3.3 for extinct *versus*
583 extant species, respectively; Figure 4B). This predator naivety, coupled with the species'
584 slow life histories, likely made megafauna especially vulnerable to new predators [34,79–81]

585 and suggests that hunting by humans could have adversely affected megafauna. Thus, a
586 network modelling approach to assessing extinction vulnerability suggests that bottom-up
587 and/or top-down processes could have selectively removed the now-extinct species from the
588 Naracoorte community. However, there remains scope to address uncertainties regarding the
589 structure of the Naracoorte network and the methods for estimating vulnerability to
590 ecological cascades. As palaeo-vegetation, invertebrate, trophic (including detailed
591 information on the diets of extinct species), and climate data improve, network models can
592 incorporate this information to build more refined networks, and include more detailed top-
593 down and bottom-up forcings to assess the plausibility of the different potential causes and
594 pathways to extinction — including what (if any) role humans played in the megafauna’s
595 demise.

596 In summary, our network modelling of Late Pleistocene Naracoorte suggests bottom-up
597 coextinction cascades and/or predator naivety and the arrival of humans could have
598 contributed to the megafauna extinction event in Sahul. Indeed, that our network models
599 showed that extinct species were vulnerable to bottom-up cascades *and* new predation
600 pressures lends support to recent research suggesting that climate change (that can shift
601 vegetation and lead to bottom-up cascades) and human arrival together drove the megafauna
602 extinction trajectories in much of south-eastern Sahul [25]. Our research, along with other
603 recent studies [19,62,82], demonstrates that network modelling is a powerful tool for
604 investigating and understanding ancient extinction events. By developing methods to model
605 whole-community responses to change and validating these methods using ancient extinction
606 events, we can also provide better estimates of the fates of contemporary communities as the
607 sixth mass-extinction event unfolds [83].

835

Figure 1

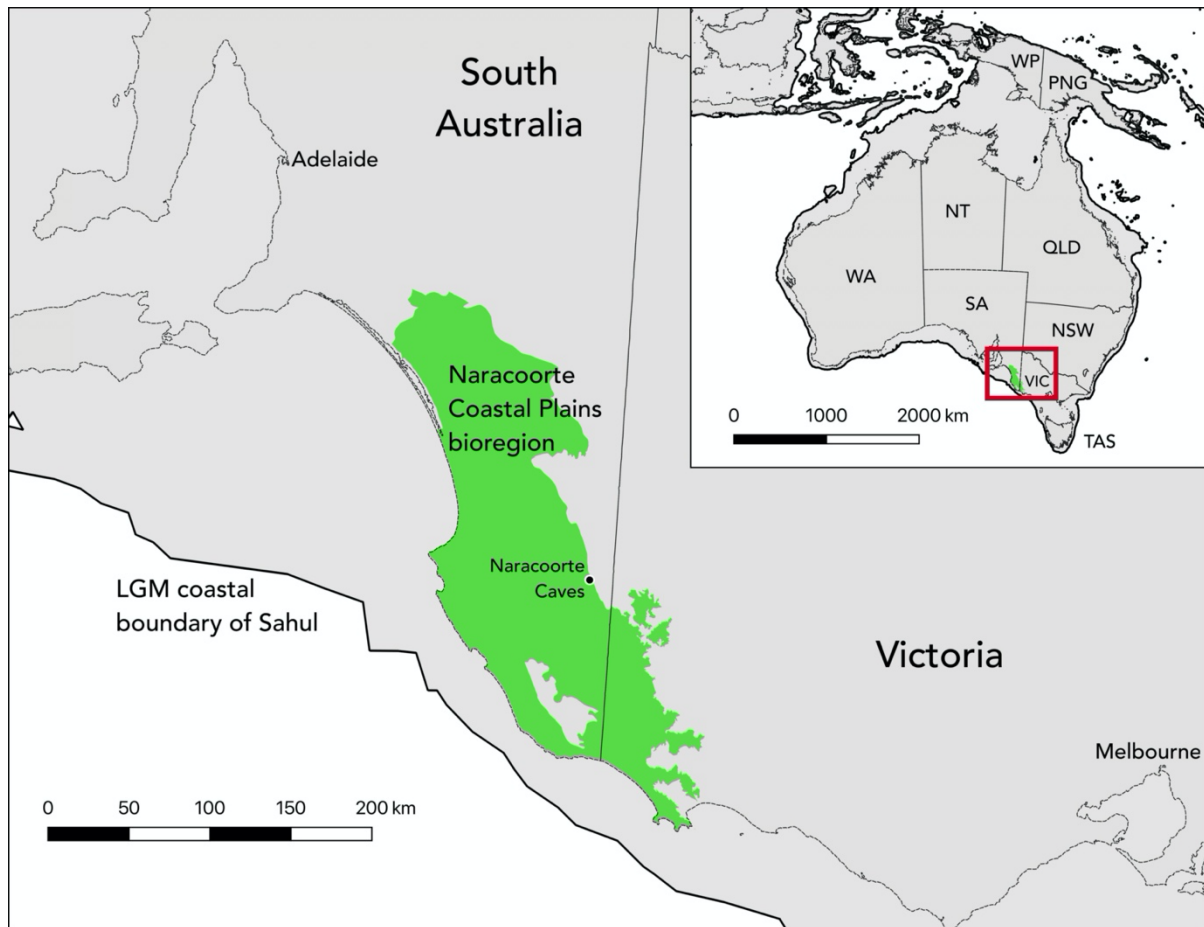

Figure 1. Sahul (top right insert) and the Naracoorte bioregion/Naracoorte Caves in south-eastern Sahul (main figure). These maps show coastline/sea level as they were during the Last Glacial Maximum (LGM; approximately 19,000 to 26,500 years ago). The grey area and thick outline indicate the land area during the LGM, the thinner lines show present-day coastlines and borders between countries and Australian states and territories, and the green area highlights the Naracoorte bioregion.

Figure 2

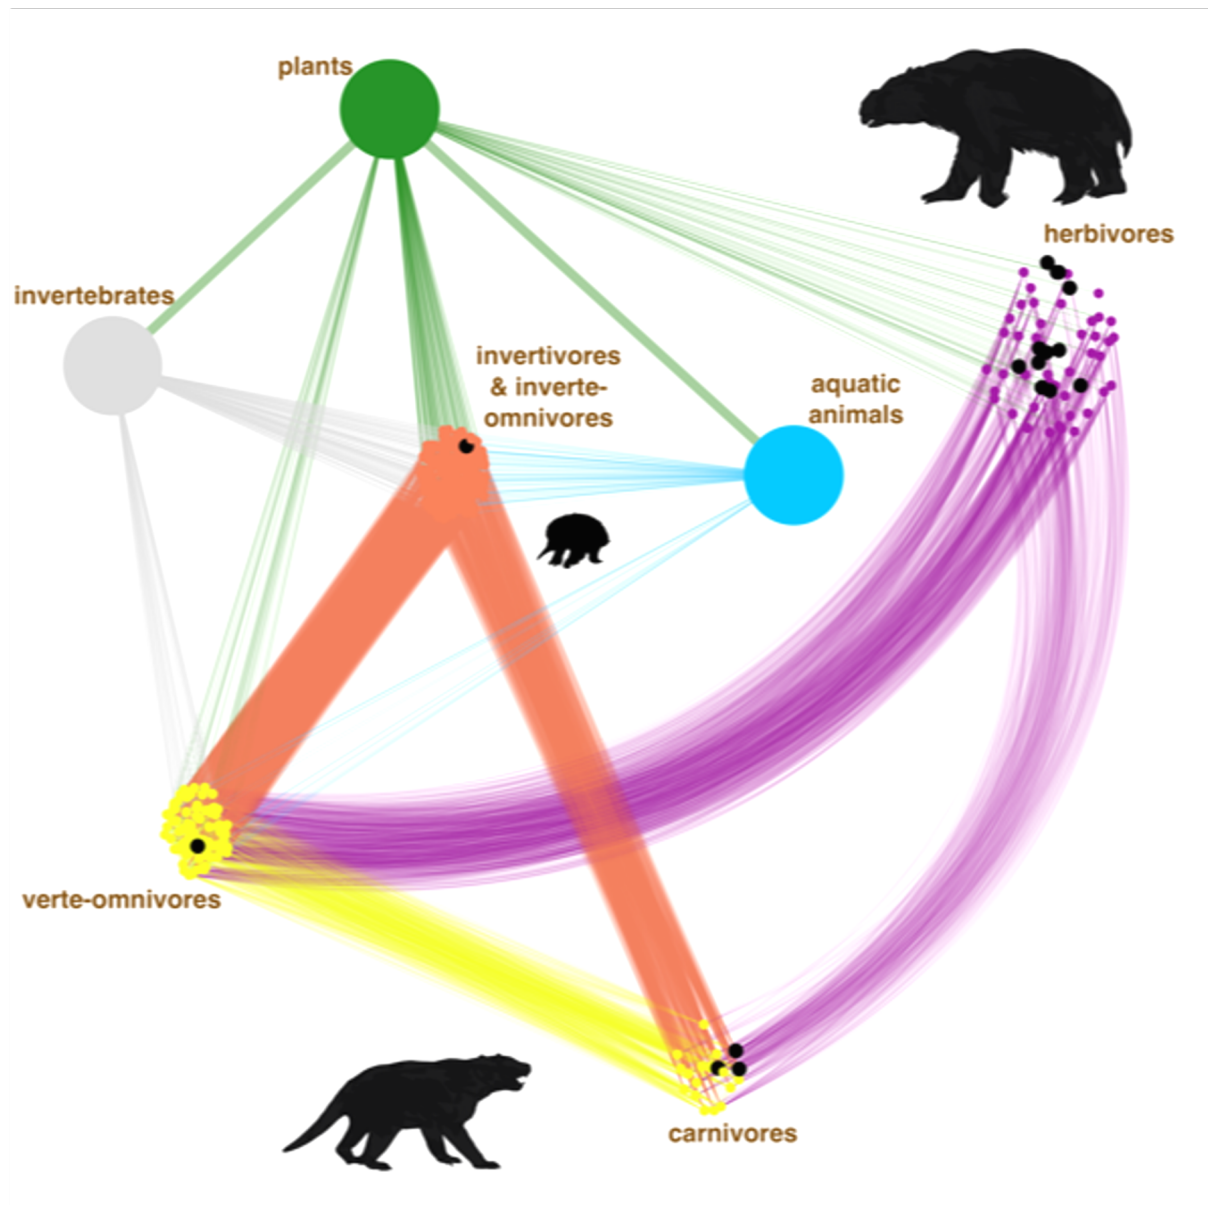

Figure 2. Example of an inferred ecological network model of the Late Pleistocene Naracoorte assemblage. Small points represent vertebrate species (nodes) and lines represent trophic interactions (links). Point colour shows trophic group (e.g., herbivores, carnivores etc), and extinct nodes are black. Due to uncertainty regarding trophic interactions, 1000 versions/models of the Naracoorte network were inferred and analysed. Plants, invertebrates and fish are shown as single large points in this figure.

Figure 3

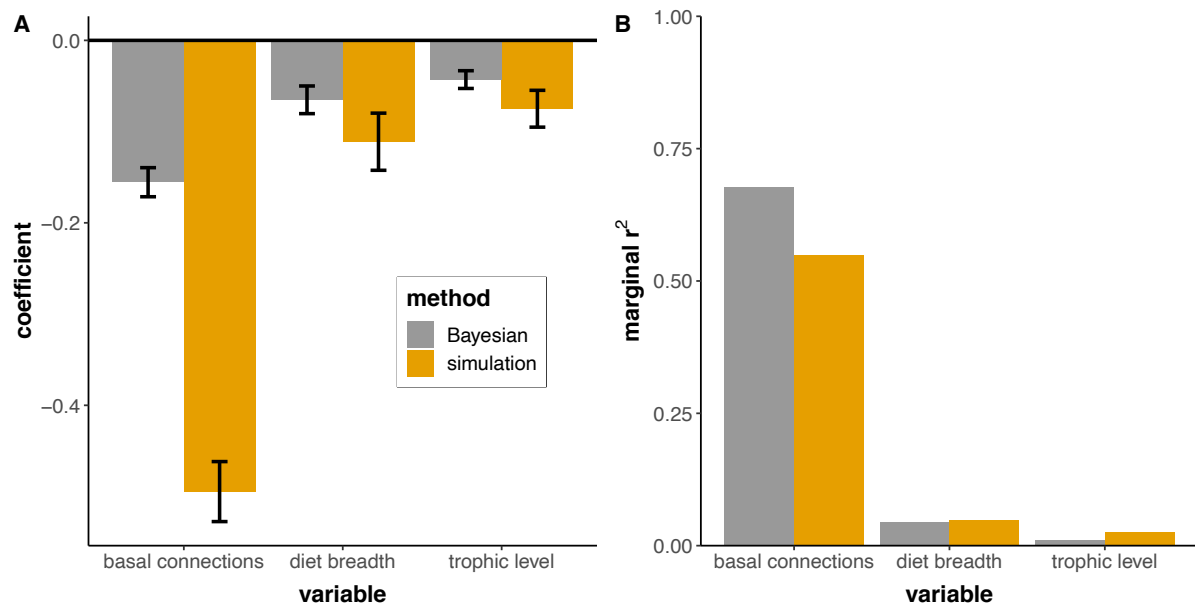

Figure 3. The effects of basal connections, diet breadth, and trophic level on vulnerability to bottom-up cascades in synthetic networks. Vulnerabilities were calculated using either a simulation or Bayesian network approach. Plot **A** shows the weighted, model-averaged coefficients of the main effects (both methods), and plot **B** shows the marginal R^2 from mixed-effects models that had either basal connections, diet breadth, or trophic level as the only fixed effect (both methods). Error bars in plot A indicate 95% confidence intervals.

Figure 4

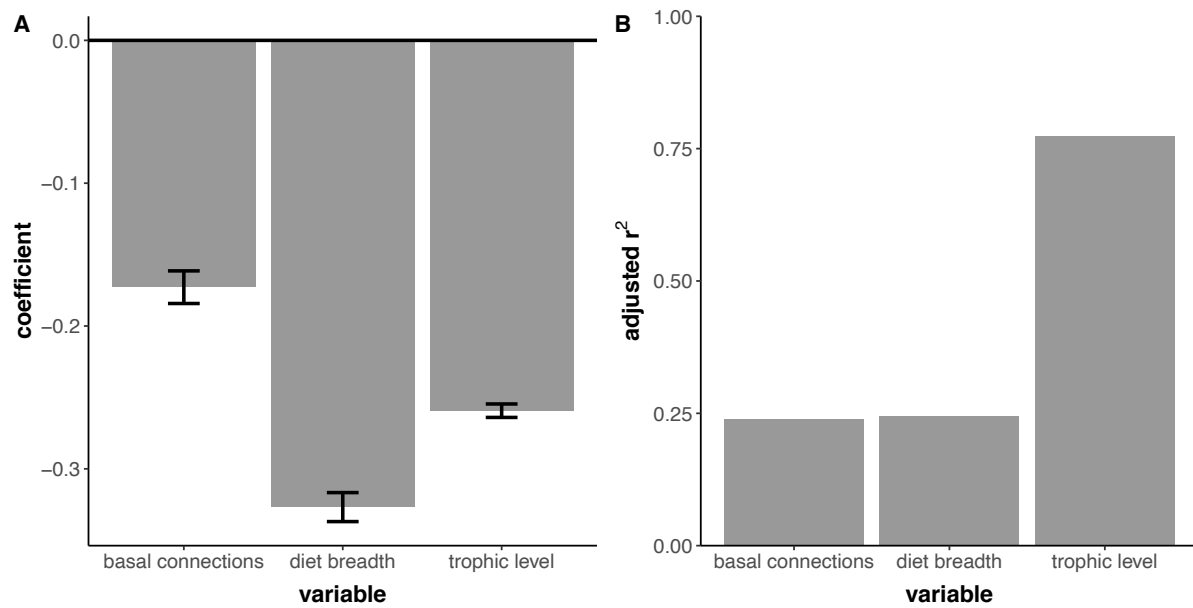

Figure 4. The effects of basal connections, diet breadth, and trophic level on vulnerability (calculated using the simulation approach) to bottom-up cascades in the Naracoorte network models. Each species' mean number of basal connections, diet breadth, trophic level, and vulnerability to bottom-up cascades was calculated, and linear regression models were fit to the mean data. Plot **A** shows the weighted, model-averaged coefficients of the main effects, and plot **B** shows the adjusted R^2 from linear regression models that had either basal connections, diet breadth, or trophic level as the only fixed effect. Error bars in plot A indicate 95% confidence intervals.

Figure 5

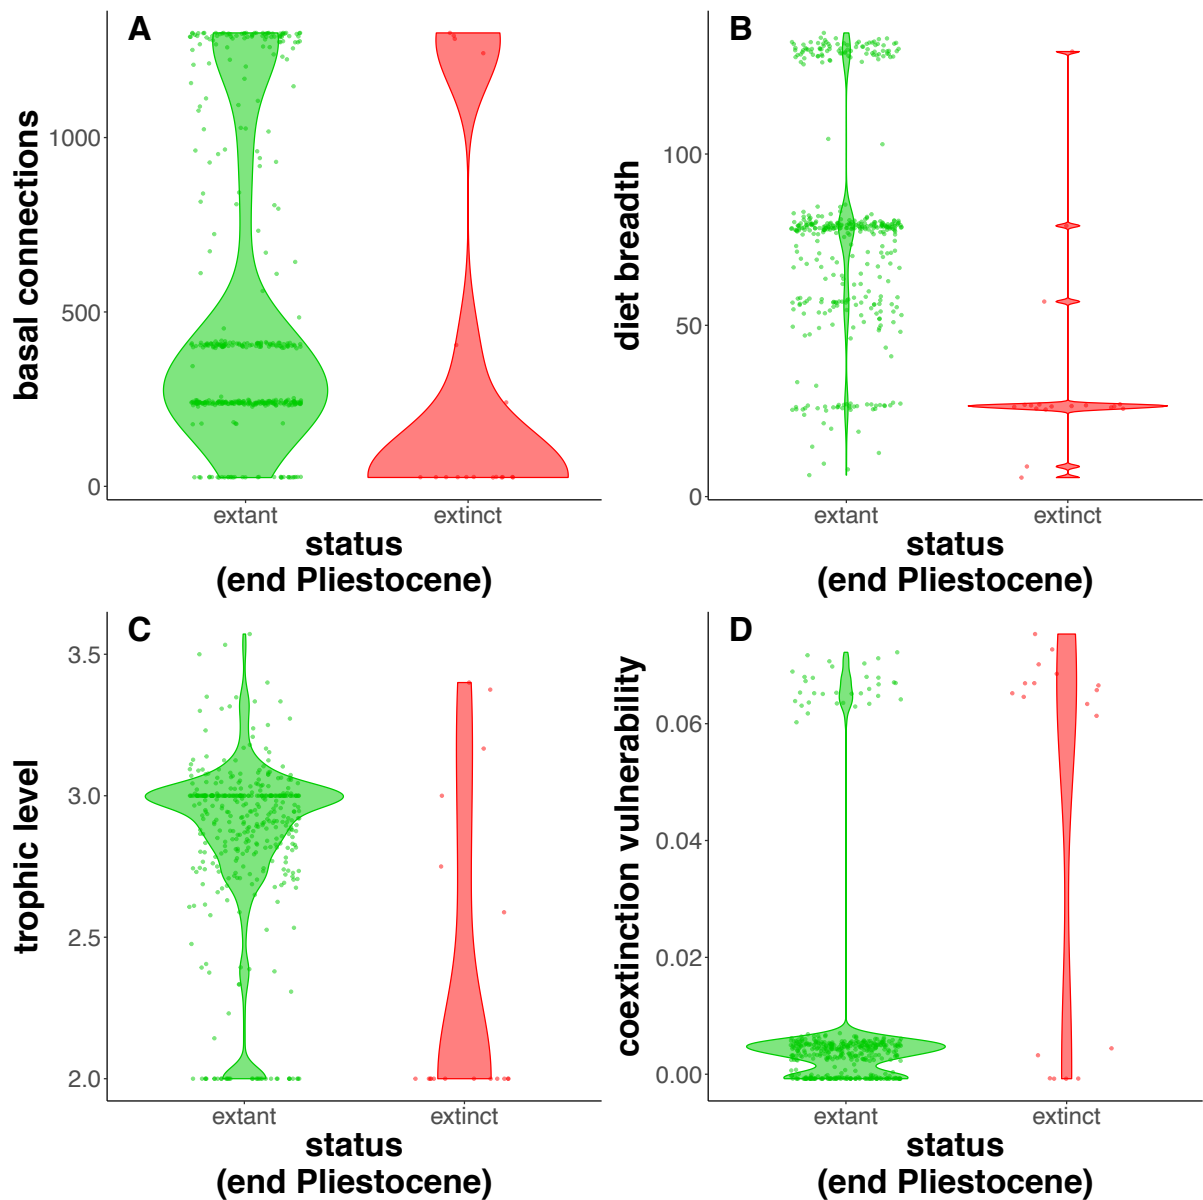

Figure 5. Comparison of species that survived into the Holocene (extant, shown in green) to those that went extinct in the Late Pleistocene (extinct, shown in red) from the Naracoorte network. Panel **A** shows the number of basal nodes (plants) connected directly and indirectly to each node via 'in' links; panel **B** shows diet breadth of each node; panel **C** indicates trophic level; and panel **D** shows the calculated coextinction vulnerability. The panels, which all include density violin plots and scatterplots, are based on each species' mean score across the 1000 Naracoorte network models.

Figure 6

Figure 6. Density plot showing results from a randomization test (20,000 replicates) comparing bottom-up coextinction vulnerability of extinct *versus* extant species from the Naracoorte network models. Each species' coextinction vulnerability was calculated using the simulation method (removing plant nodes and then removing animal nodes that no longer had connections to plant nodes). From these results, the coextinction vulnerabilities of 10 extinct and 10 extant species were sampled (with replacement), and the mean differences in coextinction between the groups calculated. This process was repeated 20 times for the results from each of the 1000 network models and used to build the density plot. The red area of the density plot indicates higher vulnerability for extinct species, and the green area indicates higher vulnerability for extant species.

Figure 7

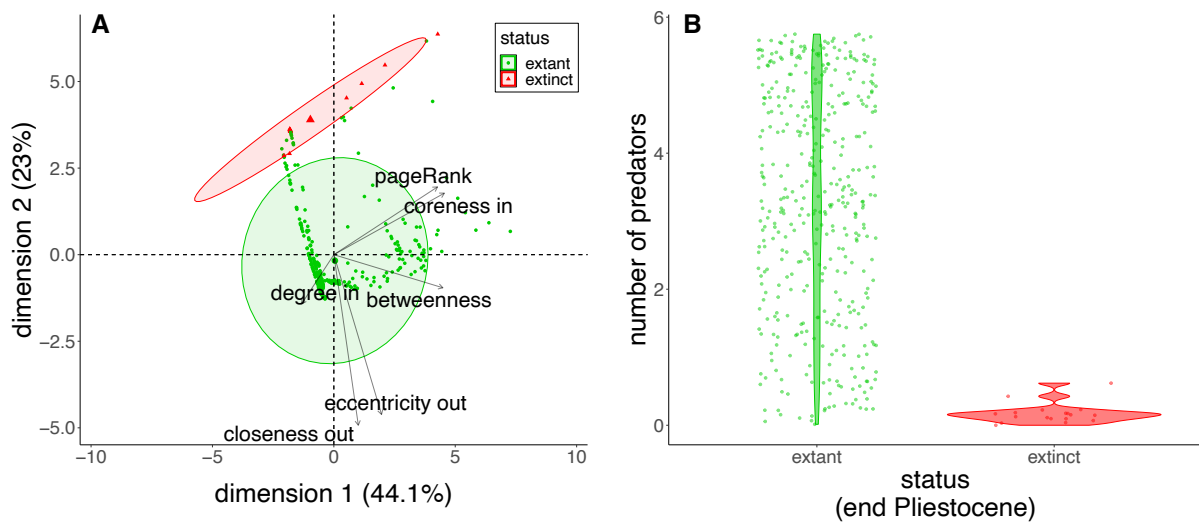

Figure 7. Comparison of extinct *versus* extant species in terms of their position in the Naracoorte trophic network. Panel **A** is a biplot of the first two principal components from a principal component analysis of six variables describing species' positions in the network. Panel **B** is a violin and scatter plot showing the number of species that preyed on each extant *versus* extinct species. We inferred 1000 models of the Naracoorte network, and from these models calculated each species' mean value of each metric for use in the principal-components biplot and predator-diversity plot.
