Abstract

The human brain consumes a disproportionate amount of energy to generate neural dynamics. Yet precisely how energetic processes are altered in neurological disorders remains far from understood. Here, we use network control theory to profile the brain's energy landscape, describing the rich dynamical repertoire supported by the structural connectome. This approach allows us to estimate the energy required to activate a circuit, and determine which regions most support that activation. Focusing on temporal lobe epilepsy (TLE), we show that patients require more control energy to activate the limbic network than healthy volunteers, especially ipsilateral to the seizure focus. Further, greater energetic costs are largely localized to the ipsilateral temporo-limbic regions. Importantly, the energetic imbalance between ipsilateral and contralateral temporo-limbic regions is tracked by asymmetric metabolic patterns, which in turn are explained by asymmetric gray matter volume loss. In TLE, failure to meet the extra energy demands may lead to suboptimal brain dynamics and inadequate activation. Broadly, our investigation provides a theoretical framework unifying gray matter integrity, local metabolism, and energetic generation of neural dynamics.

Main

Human brain function emerges from continuous neural dynamics that give rise to diverse activation states and rich rules for transitioning between states[1–5]. Those dynamics pose marked energetic demands, consuming 20% of the body's energy while comprising merely 2% of the body's weight[6]. Pathological disruptions to healthy neural dynamics and their energetic sequelae, as observed in neurological and psychiatric diseases, can have devastating consequences for cognitive function and behavior. One prototypical example is epileptic seizures, which are transient periods of pathological hypersynchronous neuronal activities[7]. Seizures consume significant energy and instantly disrupt ongoing brain dynamics, causing marked behavioral disturbances[8,9]. Despite their transience, the impact of seizures on brain function can linger well beyond seizure termination, especially in patients with drug-resistant focal epilepsy, such as temporal lobe epilepsy (TLE). Neuropsychological assessments performed during the interictal period, *i.e.*, when patients are not suffering from seizures, reveal persistent deficits in multiple cognitive and affective domains[10–13], indicating the presence of prolonged disruptions to normal brain dynamics. Little is known about this pervasive neural dysfunction throughout the vast temporal epochs between seizures, its relation to brain energetics, and its potential dependence upon the brain's structural backbone.

TLE is marked by widespread alterations in brain structure, which—importantly—extends beyond the seizure foci[14–16]. Concordantly, epileptogenic regions evince persistent hypometabolism during interictal periods[17]. The severity of both structural damage and hypometabolism is associated with cognitive decline in TLE patients[18–20], suggesting that chronic neural dysfunction might be rooted in a reduced baseline metabolism underpinned by compromised structural integrity. Regional hypometabolism could hamper the attainment and maintenance of healthy activation levels, in turn decrementing the brain's dynamic repertoire and

2

61   clamping cognitive function. Examples of such altered dynamics in TLE abound, spanning
62   reduced language network flexibility (*i.e.*, fewer state transitions)[21], reduced memory network
63   flexibility[22], delayed information flow, and slower activation spreading times[23]. Despite these
64   pervasive alterations in dynamics, metabolism, and structure, little is known about the
65   mechanistic relationships between them.
66   To formally assess how damage to structural connectivity disrupts energetic generation of
67   brain dynamics, we use network control theory (NCT), a powerful approach from systems
68   engineering typically deployed to design and manage technological, robotic, and communication
69   systems. NCT allows us to evaluate the energetic cost of brain states—and transitions between
70   them—as a function of the underlying network architecture. We begin by stipulating a dynamical
71   model whereby activity is constrained to spread along structural connections (**Figure 1a**). Using
72   this model, we can quantify the control energy required to move between any two states or
73   patterns of activity[24]. Prior work has shown that the control energy required to transition between
74   states varies with cognitive demand[25], decreases over development[26], and is altered in psychiatric
75   disorders[27,28]. Prior studies have also demonstrated that control energy can be causally
76   manipulated by brain stimulation[29] and antipsychotic medication[25]. These efforts lay important
77   groundwork for our use of NCT to model the structurally-constrained energetic processes of
78   brain state transitions in patients with TLE, by supporting its feasibility, ensuring its
79   methodological rigor, and underscoring its biological relevance.
80   Although a generic artificial system could hypothetically visit any activation state, evidence
81   suggests that the brain preferentially visits some states more often than others[4,30,31]. These
82   preferential states can be defined by the co-activation of regions that are functionally coupled at
83   rest[32,33]. Such so-called *intrinsic connectivity networks* (ICNs) can also be detected during task
84   performance, and have been shown to support a range of cognitive processes[32,34,35]. Here, we
85   study the efficient attainment of eight such preferential states[33,36], whereby only regions in a
86   given ICN are active (**Figure 1b**). Then, we use NCT to simulate transitions among preferential
87   states and to estimate the associated energy costs, thereby probing the brain's efficiency and
88   integrity in the presence of TLE. Our simulations evaluate two transition types: (1) *reaching
89   transitions*, where the brain moves from a theoretical baseline to a preferential state (**Figure 1c**);
90   and (2) *switching transitions*, where the brain moves between two preferential states (**Figure
91   1d**). By estimating the control energy for *reaching transitions*, we determine which preferential
92   states are difficult to reach; that determination informs our understanding of the ICNs impacted
93   by TLE. Subsequently, we compute control energy for *switching transitions*, which allows us to
94   identify the regions that tend to carry the greatest energetic burdens in supporting the brain's
95   dynamical repertoire.
96   After using NCT to unravel the energetic basis of brain dysfunction in TLE, we next dig
97   deeper into the neurophysiological underpinnings of control energy. In the absence of any
98   external input to the brain (*e.g.*, brain stimulation), control energy is thought to track the cost of
99   endogenous resources associated with internal cognitive demand[25,37]. However, there is as yet no
100   precise evidence linking this metric to a direct readout of such resources. Here we provide

101   exactly such evidence. As part of presurgical evaluation in patients with TLE,
102   fluorodeoxyglucose (FDG)-PET is commonly performed interictally to measure baseline
103   metabolic levels. Leveraging this additional piece of information, we can verify whether regions
104   that show altered energetic efficiency in facilitating brain state transitions also present with
105   metabolic anomalies. Moreover, we can determine how both the theoretical and empirical
106   measures of energy costs are related to the underlying structural integrity of those regions.

107   In this study, we enrolled 60 TLE patients and 50 demographically matched healthy controls
108   (HCs) (**Table 1**), who underwent an MRI scanning session including both a high angular
109   resolution diffusion imaging (HARDI) scan and a T1-weighted (T1w) anatomical scan. Among
110   the enrolled patients, 50 also received an FDG-PET scan as part of their presurgical evaluation.
111   From each participant's HARDI data, we generated a structural connectome and estimated the
112   control energy required to perform all *reaching* and *switching transitions*. Then, we tested for
113   energetic deficiencies in TLE by comparing control energy between patients and HCs. We
114   showed that TLE patients present with an energetic deficiency in reaching a preferential state
115   predominantly comprised of limbic regions. This deficiency was due to excessive energy costs
116   associated with activating the limbic network ipsilateral to the patient's seizure focus. When
117   considering *switching transitions*, we found that the mesial and inferior parts of the ipsilateral
118   temporal lobe demanded greater energy consumption in TLE than in HCs. These increased costs
119   of regulating brain dynamics incurred by TLE patients limit their capacity to activate and
120   maintain desired brain states, potentially leading to dysfunction. Furthermore, we found that this
121   energetic imbalance between ipsilateral mesial and inferior temporal regions and their
122   contralateral counterparts were accompanied by similar asymmetries in metabolic patterns, both
123   of which are rooted in a corresponding asymmetry of underlying gray matter volume loss.

Figure 1. Schematic of methods. (a) Based on a simplified noise-free, linear, continuous-time, and time-invariant model of neural dynamics, we simulate energetic processes during brain state transitions instantiated upon and constrained by the structural connectome (matrix A). Two types of control energy (a quadratic function of u) are depicted: the minimum control energy required to drive the brain from an initial state $[x(0)]$ to a final state $[x(T)]$ using a specific set of control nodes (whole brain, matrix B); the optimal control energy additionally constrains the length of the trajectory between states. (b) Eight preferential brain states are defined according to the known intrinsic connectivity networks (ICN)[32,33]. Within each state, regions from a specific ICN are activated at a magnitude of 1, whereas the rest of the brain remains at 0 (inactivated). These preferential brain states constitute the initial and

124

final states of our simulations. (c) We then simulate the energetic inputs required to activate each of the preferential brain states from a theoretical baseline (*i.e.*, activity magnitude of 0). Next, we estimate the optimal control energy consumed during each of the activation processes across the whole brain for each subject. (d) We also simulate transitions between preferential brain states, and estimate the minimal control energy consumed at each brain region for each subject. Abbreviations: VIS, visual network; SMN, somatomotor network; DAN, dorsal attention network; SAL/VAN, salience/ventral attention network; CONT, executive control network; DMN, default mode network; SUB, subcortical network.

125

Results

127   We started our analyses by verifying that the imaging data quality was comparable between
128   the two experimental groups (**Table 1**). Next, for each participant, we reconstructed a structural
129   white matter network as a weighted undirected adjacency matrix comprised of 122 cortical and
130   subcortical regions (see details in *Methods*), which formed the basis of our NCT analyses (*e.g.*,
131   matrix A in **Figure 1a**). We observed that TLE patients presented lower matrix density and total
132   weight (*i.e.*, sum of all edge weights) than HCs (**Table 1**), which is in accord with the well-
133   recognized white matter abnormalities in TLE[38,39]. To minimize the influence of demographic
134   and data quality metrics on our subsequent statistical analyses, we regressed them out from all
135   imaging derivates using linear regression (see *Methods*).

Table 1. Sample demographic and clinical characteristics.

Experimental Group (N)	**TLE** (60)	**HC** (50)	*T/χ^2*	*P*

Continuous variables were presented as mean ± standard deviation. Abbreviations and definitions: TLE, patients with temporal lobe epilepsy; HC, healthy controls; HARDI, high angular resolution diffusion imaging; FIAS, focal impaired awareness seizure; FAS, focal aware seizure; FBTCS, focal to bilateral tonic-clonic seizure; AED, anti-epileptic drug. The quality of T1-weighted images was assessed with an image quality rating and the total intracranial volume produced with the Computational Anatomy Toolbox (CAT12)[99]. The quality of HARDI data was assessed with a neighboring correlation index[79] which quantified the similarity between low-b volumes with similar gradient directions, as well as with the mean framewise displacement[78] as a measure of head motion. Seizure focus was classified as: left temporal (LT) and right temporal (RT). Temporal pathology was diagnosed by neuroradiologists based on presurgical MRI scans as: normal brain MRI (NB); hippocampal sclerosis (HS); other pathologies (Other), such as tumor, focal cortical dysplasia, encephalocele, etc. FBTCS history was sorted as: *none*, patients who had never had any FBTCS events during their lifetime; *remote*, patients who had experienced FBTCS in the past, but none for one year or more prior to scanning; *current*, patients who had recurrent FBTCS within one year prior to scanning[44,100]. For continuous variables, independent *t*-tests were conducted. For categorical variables, chi-square tests were conducted. Significant differences were highlighted in bold.

138

Simulated activation of intrinsic connectivity networks

139

140   Our first research question pertained to the energetic costs associated with *reaching* each
141 preferential brain state. Specifically, we examined the extent to which TLE patients exhibited
142 energetic abnormalities during the activation of eight canonical ICNs[33,36], including the visual,
143 somatomotor, dorsal attention, salience/ventral attention, limbic (including amygdala and
144 hippocampus), executive control, default mode, and subcortical networks (**Figure 1b**). We used
145 the optimal control framework[26,29,36,40] to model how the brain's underlying structural network
146 facilitated transitions from an initial baseline state to each preferential (final) state. Here, the
147 initial state was set at a theoretical baseline with activity magnitude in all regions at 0. For each

148   of our 8 preferential states, the activity magnitude of regions within a specific ICN was set to 1,
149   while the rest of the brain remained at 0[26]. Thus, these *reaching transitions* simulated the rise of
150   activity in the target ICN from a mean-centered baseline, mimicking the activation process
151   triggered by specific cognition operations. For this model, an optimal solution of the control
152   energy needed at each region can be produced by constraining both the energy costs and the
153   length of the transition trajectory based on the underlying network topology[37]. As previously[37],
154   we referred to this solution as the *optimal control energy* (OCE), and summarized it globally as a
155   measure of the brain's energetic efficiency (**Figure 1c**, see details in *Methods*). For each
156   participant, we estimated the global OCE during each *reaching transition*. We regressed the
157   confounding variables out of these global OCE estimates and compared the residuals between
158   our two groups using a permutation-based *t*-test[41], an approach that simultaneously corrects for
159   multiple comparisons by controlling the family-wise error rate[42]. We found that TLE patients
160   required greater global OCE to activate the limbic network compared to HCs (Welch's $t_{108}=3.80$,
161    $P_{corr}=0.002$). The global OCE needed to activate other ICNs did not significantly differ between
162   the two groups (Welch's $|t_{108}\text{'s}|<1.55$, $P_{corr}>0.609$) (**Figure 2**). This finding suggests that it is
163   energetically more challenging for TLE patients to specifically activate the limbic network.

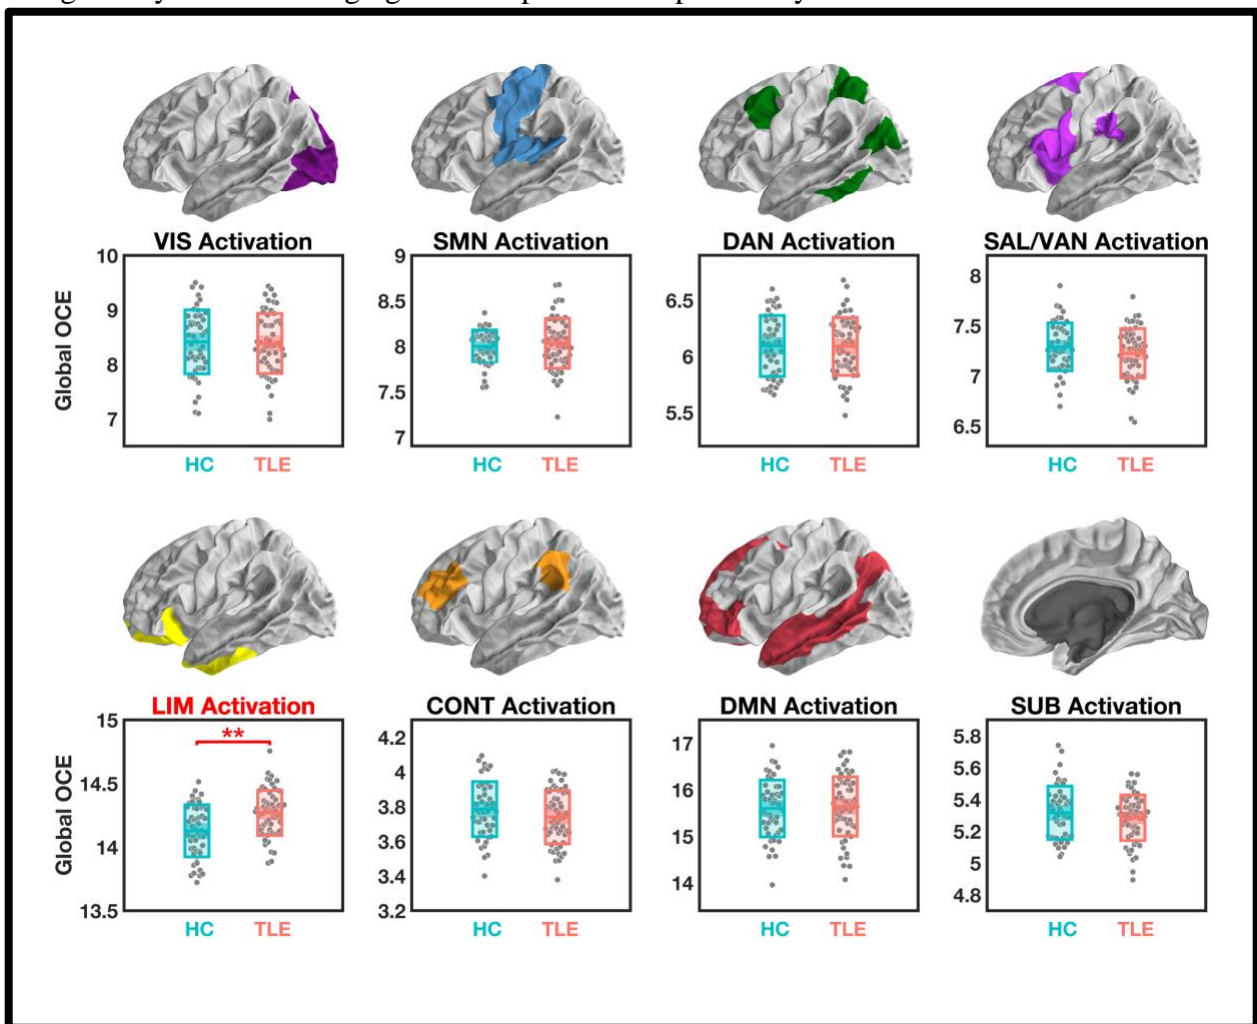

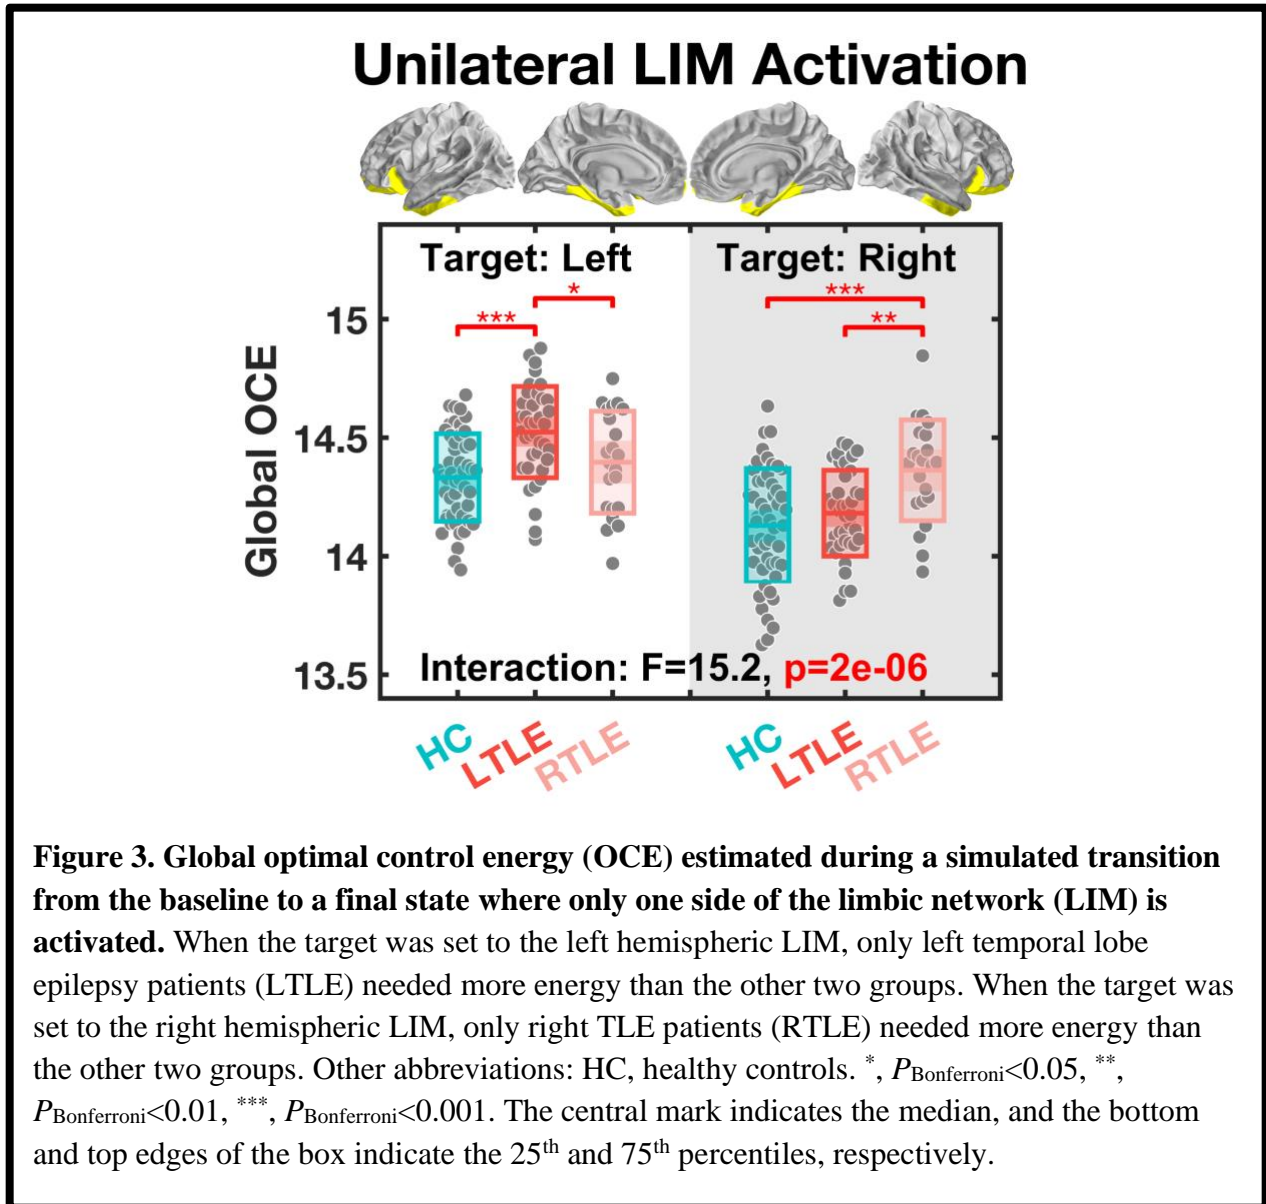

164

Figure 2. Global optimal control energy (OCE) estimated during simulated activation of intrinsic connectivity networks. After correction for multiple comparisons, significant group differences were only found for the simulated activation of the limbic network (LIM), which demanded more global OCE in patients with temporal lobe epilepsy (TLE) compared to healthy controls (HC). Other abbreviations: VIS, visual network; SMN, somatomotor network; DAN, dorsal attention network; SAL/VAN, salience/ventral attention network; CONT, executive control network; DMN, default mode network; SUB, subcortical network. **, $P_{corr} < 0.01$. The central mark indicates the median, and the bottom and top edges of the box indicate the 25th and 75th percentiles, respectively.

165

166   In the above analysis, our preferential states were defined with ICNs extended into both
167   hemispheres. However, seizures in our enrolled TLE patients were exclusively of unilateral
168   origin, *i.e.*, from either the left or the right temporal lobe. This laterality of seizure focus suggests
169   that the energetic inefficiency we observed in these patients may be asymmetric, especially with
170   regard to the limbic network, which includes both the epileptogenic temporal lobe and its
171   contralateral counterpart. To probe this asymmetry, we re-simulated the *reaching transition* for
172   the limbic network twice, once to activate limbic regions in the left hemisphere only, and once to
173   activate regions in the right hemisphere. Although such a hemispheric restriction of activation is
174   unlikely to occur in the brain, the simulation offers an opportunity to assess the laterality of the
175   pathological burden observed in TLE patients. When examining lateralized global OCE, we
176   found a significant hemisphere-by-group interaction [$F_{(2,107)}=15.20$, $P=2\times10^{-6}$] (**Figure 3**),
177   demonstrating that TLE patients required more energy to activate the limbic network ipsilateral
178   to the seizure focus. More specifically, TLE patients with a left-sided seizure focus required
179   more energy to activate the left-hemispheric limbic network (vs. right TLE: $P_{Bonferroni}=0.048$; vs.
180   HC: $P_{Bonferroni}=4\times10^{-5}$), whereas TLE patients with a right-sided seizure focus required more
181   energy to activate the right-hemispheric limbic network (vs. left TLE ($P_{Bonferroni}=0.007$); vs. HC:
182    $P_{Bonferroni}=2\times10^{-4}$). By contrast, we observed no significant differences between TLE patients and
183   HCs in the energy needed to activate the contralateral limbic network ($P_{Bonferroni}$'s>0.588). Thus,
184   the extra energetic costs associated with limbic network activation in TLE can be attributed to
185   the increased energetic needs of the ipsilateral hemisphere, but not of the contralateral one.

Figure 3. Global optimal control energy (OCE) estimated during a simulated transition from the baseline to a final state where only one side of the limbic network (LIM) is activated. When the target was set to the left hemispheric LIM, only left temporal lobe epilepsy patients (LTLE) needed more energy than the other two groups. When the target was set to the right hemispheric LIM, only right TLE patients (RTLE) needed more energy than the other two groups. Other abbreviations: HC, healthy controls. *, $P_{\mathrm{Bonferroni}}<0.05$, **, $P_{\mathrm{Bonferroni}}<0.01$, ***, $P_{\mathrm{Bonferroni}}<0.001$. The central mark indicates the median, and the bottom and top edges of the box indicate the 25th and 75th percentiles, respectively.

186

187 *Regional energetic efficiency in supporting brain state transitions*

188 Empirical brain dynamics depend not only on the attainment of different states, but even
189 more on the flexible transitions among them, supported by brain regions consuming energy at
190 different efficiencies. While our *reaching transition* simulations enabled us to identify global
191 energetic inefficiency during limbic network activation in TLE patients, such transitions are not
192 necessarily representative enough, *i.e.*, the brain does not revisit a specific baseline each time,
193 but rather, continuously transitions between different states. Thus, to better profile regional
194 energetic efficiency, we extended our investigation to examine *switching transitions* among our
195 preferential states, as a closer approximation of empirical brain dynamics[36]. For each subject, we
196 modeled a total of 64 pairwise transitions, including both reciprocal state transitions and single
197 state persistence (*i.e.*, transition starts and ends at the same state) among the eight ICN-defined
198 preferential states (**Figure 1d**). To allow maximal flexibility during the simulated transitions, we

10

199 estimate the *minimal control energy* (MCE), which can be obtained by only constraining for the
200 control input to facilitate the designated transition regardless of its trajectory[37]. For each region,
201 we averaged the MCE across all 64 transitions as a region-specific metric of energetic efficiency
202 at the individual level. To enhance statistical power[38,43,44], we mirror-flipped the regional MCE
203 of the right TLE patients to group metrics according to the laterality of the seizure focus[38,44,45].
204 This procedure was done after confound regression Z-standardization of each patient's regional
205 MCE relative to HC data. Thus, instead of comparing raw values of regional MCE from mixed
206 hemispheric origin between patients and HCs, we performed a permutation-based one-sample *t*-
207 test on patients' Z-scores of the 122 regions, to identify abnormal regional energetic efficiencies
208 within ipsilateral and contralateral hemispheres, respectively (see *Methods* for further details).
209   After applying a multiple comparison correction, we found that regional MCE was
210 significantly elevated in TLE patients within the ipsilateral hemisphere only. This elevation
211 occurred specifically in regions such as the temporal pole (t_{59}=5.40, P_{corr}=10^{-4}), inferior temporal
212 gyrus (t_{59}=5.03, P_{corr}=5×10^{-4}), amygdala (t_{59}=6.01, P_{corr}=10^{-5}), hippocampus (t_{59}=5.24,
213 P_{corr}=2×10^{-4}), parahippocampal gyrus (t_{59}=4.54, P_{corr}=0.003), and fusiform gyrus (t_{59}=4.93,
214 P_{corr}=7×10^{-4}), as well as the isthmus of the cingulate gyrus (t_{59}=4.17, P_{corr}=0.011, rest of the
215 brain: $|t_{59}$'s$|$<3.41, P_{corr}>0.114) (**Figure 4a**). No significant effects were observed in the
216 contralateral hemisphere. In TLE, these regions required more energy to facilitate the same brain
217 state transitions than in HC. Furthermore, this energetic inefficiency was largely located in the
218 ipsilateral temporo-limbic regions, consistent with our previous results showing the costly
219 activation of the limbic network in TLE patients.
220   It remains to be determine, however, whether simulating transitions among ICN-defined
221 brain states can provide a representative overview of all possible brain state transitions. Thus, we
222 stringently assessed the robustness of the above findings by comparing them to MCE values
223 derived from transitions between 100,000 pairs of random initial and final states. These random
224 states were generated following a Gaussian distribution of activity magnitude across the 122
225 regions with a mean of 1 and a standard deviation of 0.1[26]. This finite repository serves as an
226 approximation of all possible state transitions when no *a priori* brain states are explicitly defined.
227 We adopted the same minimal control framework as above, and obtained the Z-transformed
228 regional energy estimates. Consistent with our primary findings, we found significantly higher
229 MCE in the ipsilateral hemisphere only, including regions such as temporal pole (t_{59}=4.57,
230 P_{corr}=0.003), inferior temporal gyrus (t_{59}=4.45, P_{corr}=0.004), amygdala (t_{59}=3.96, P_{corr}=0.022),
231 hippocampus (t_{59}=4.44, P_{corr}=0.004), parahippocampal gyrus (t_{59}=5.33, P_{corr}=2×10^{-4}), and
232 fusiform gyrus (t_{59}=5.30, P_{corr}=2×10^{-4}), as well as the isthmus of the cingulate gyrus (t_{59}=4.83,
233 P_{corr}=0.001, rest of the brain: $|t_{59}$'s$|$<3.30, P_{corr}>0.156) (**Figure 4b**). Thus, these randomly
234 generated brain states yielded results matching those observed from ICN-defined brain states,
235 supporting the notion that our preferential states appropriately represented the repertoire of
236 empirical brain dynamics.

Figure 4. Regional energy efficiency differences between temporal lobe epilepsy (TLE) patients and healthy controls (HC). (a) We estimated the minimal control energy consumption of each region during all transitions between the brain states defined by intrinsic connectivity networks (ICNs). In the hemisphere ipsilateral to the seizure focus, we found significantly higher energy consumption in TLE patients than in HC among several temporo-limbic regions. (b) We then estimated the minimal control energy consumption of each region during transitions between 100,000 pairs of initial $[x(0)]$ and final states $[x(T)]$ with randomly generated activity magnitudes. Concordant results were found, showing that the patients needed significantly higher control energy in the ipsilateral temporo-limbic regions. The box plots depict the deviation scores (Z) of energy consumption of TLE patients in reference to HC. Only regions with significant group differences after multiple comparison corrections are displayed, including the isthmus of the cingulate gyrus (Isthmuscingulate-1),

237

> fusiform (Fusiform-2), temporal pole (Temporalpole-1), inferior temporal gyrus (Inferiortemporal-1), parahippocampal gyrus (Parahippocampal-1), amygdala, and hippocampus.

238

Biological validation of the brain's energetic inefficiency in TLE

240   Through NCT, we have established that TLE is associated with energetic inefficiency during
241 simulated brain dynamics, not only with respect to attaining preferential states, but also in
242 transitioning among them. Next, we sought to validate our findings using an independent
243 measurement of neurophysiological energy consumption, FDG-PET. FDG-PET is a common
244 clinical investigation used for seizure focus localization, and allows probing brain metabolism *in*
245 *vivo* by measuring regional glucose uptake. Here, FDG-PET was acquired in a subset of 50 TLE
246 patients during their presurgical evaluation. In the absence of HC data as baseline, we used data
247 from the contralateral hemisphere in the same patient as a reference. After confound regression,
248 we generated a laterality index (LI) of glucose uptake for each region (see *Methods* for details).
249 A negative LI indicated lower ipsilateral metabolism than contralateral, whereas a positive LI
250 indicated higher ipsilateral metabolism than contralateral. This relative definition of hypo- vs.
251 hypermetabolism is commonly used in clinical settings[46]. Leveraging this measure of metabolic
252 integrity, we sought to identify the neurophysiological basis of the energetic inefficiency
253 observed in our TLE patients.

254   Our first and most straightforward observation was that all the regions with disrupted
255 energetic profiles captured by our NCT analyses — ipsilateral temporal pole, inferior temporal
256 gyrus, amygdala, hippocampus, parahippocampal gyrus, fusiform gyrus, and isthmus of
257 cingulate gyrus — also exhibited ipsilateral hypometabolism (permutation-based one-sample *t*-
258 test correcting for multiple comparisons, **Supplementary Table 1, Figure 5a**). To expound on
259 this observation, we also calculated LIs of the regional MCE in these regions, and tested
260 bivariate correlations between the 7 pairs of LIs (i.e., one for MCE and one for glucose uptake)
261 with a permutation-based product-moment correlation controlling for multiple comparisons. We
262 found significant correlations between LIs at the temporal pole (R_{49}=-0.37, P_{corr}=0.049),
263 amygdala (R_{49}=-0.62, P_{corr}=8×10^{-6}), hippocampus (R_{49}=-0.60, P_{corr}=3×10^{-5}), parahippocampal
264 gyrus (R_{49}=-0.50, P_{corr}=0.002), and the fusiform gyrus (R_{49}=-0.39, P_{corr}=0.036), but not within
265 the inferior temporal gyrus (R_{49}=-0.34, P_{corr}=0.096) or isthmus of cingulate gyrus (R_{49}=-0.22,
266 P_{corr}=0.551) (**Figure 5b-h**). These results suggest that the regions where TLE patients show
267 greater control energy needs also show greater *hypo*metabolism (*i.e.*, lower metabolic baseline)
268 with respect to their contralateral counterparts.

269   One common reason for a region to exhibit hypometabolism is the loss of local structural
270 integrity as manifest by gray matter atrophy[47,48]. Accordingly, within the above-mentioned
271 regions, we also examined whether the LI of control energy was correlated with the LI of gray
272 matter volume. We found a significant correlation between energy and volume LIs in the
273 hippocampus only (R_{49}=-0.47, P_{corr}=0.005; all other regions had $|R_{49}|$'s<0.32 and P_{corr}'s>0.167).
274 This finding indicates that greater gray matter volume loss in the hippocampus is associated with

13

275   greater control energy needs. Interestingly, a bootstrapped mediation analysis focusing on the

276   hippocampus found that the LI of glucose uptake provided full mediation of the association

277   between LI of gray matter volume and LI of control energy (β=-0.125, P=0.016, **Figure 5i**).

278   Thus, the loss of local structural integrity may serve as a substrate leading to a decline in baseline

279   regional metabolism, which in turn engenders inefficient control of brain dynamics.
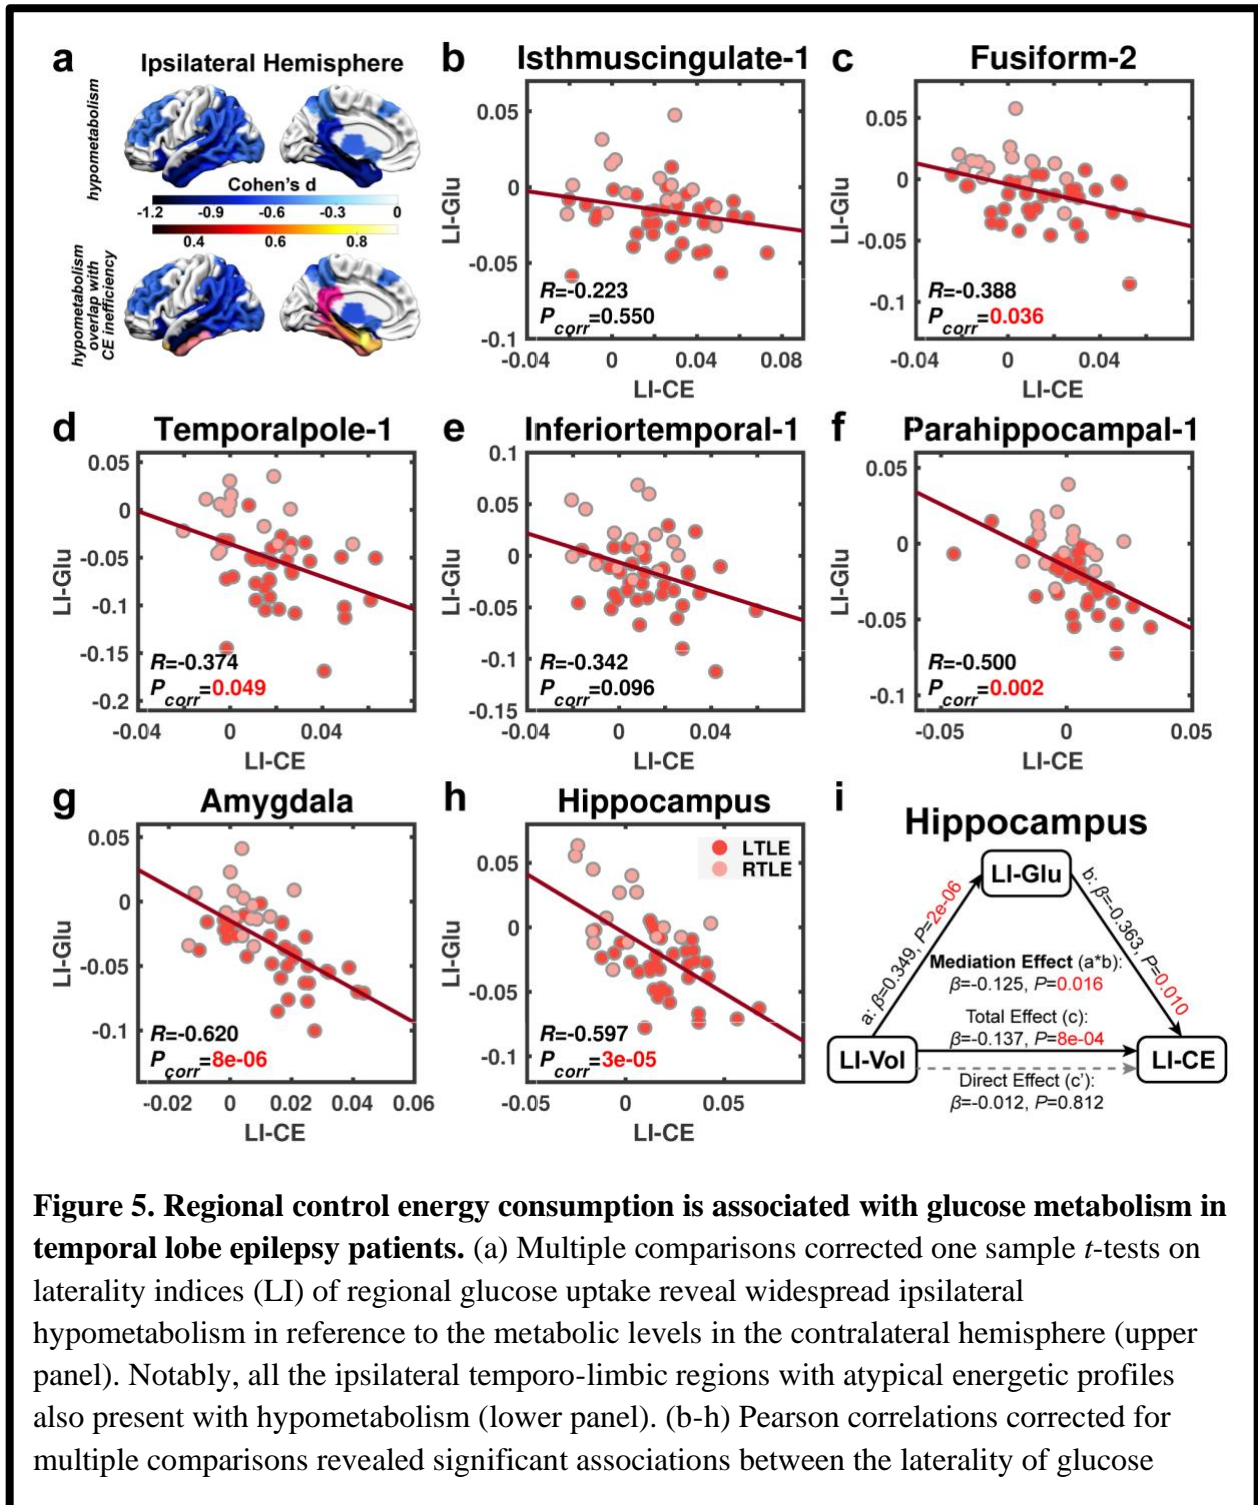

Figure 5. Regional control energy consumption is associated with glucose metabolism in temporal lobe epilepsy patients. (a) Multiple comparisons corrected one sample *t*-tests on laterality indices (LI) of regional glucose uptake reveal widespread ipsilateral hypometabolism in reference to the metabolic levels in the contralateral hemisphere (upper panel). Notably, all the ipsilateral temporo-limbic regions with atypical energetic profiles also present with hypometabolism (lower panel). (b-h) Pearson correlations corrected for multiple comparisons revealed significant associations between the laterality of glucose

280

14

uptake and minimal control energy consumption during all the transitions between the states defined by intrinsic connectivity networks (ICN), most prominently in the limbic regions, whereas the side with lower glucose metabolic baseline consumes more control energy. Corrected P-values (P_{corr}) are depicted. (i) A mediation analysis is performed on the hippocampus, where the association between the laterality of gray matter volume (LI-Vol) and control energy (LI-CE) is also found to be significant. We found that the laterality of glucose uptake (LI-Glu) provides a full mediation of the association between the former two variables. The significance of the mediation effect was assessed using bootstrapped confidence intervals.

281

Discussion

283   Pathological disruptions to normal brain dynamics in patients with drug-resistant epilepsy are
284 associated with both transient and enduring detrimental effects on brain function[10,49], which can
285 significantly compromise quality of life. Developing treatments to alleviate such impairments is
286 challenging owing to our limited understanding of how pathological conditions such as TLE alter
287 energetic processes needed to facilitate desired brain dynamics. To this end, the recent
288 development of network control theory has provided new opportunities to profile the energy
289 landscape of the brain during simulated neural dynamics in which activity spreads along the
290 structural connectome. Leveraging this framework, we showed that TLE patients required more
291 control energy to activate the limbic network compared to HCs. In particular, this increased
292 energy was localized to the limbic network ipsilateral to patients' seizure focus. Further, we
293 quantified regional energy profiles during transitions between different brain states, and found
294 that the mesial and inferior parts of the ipsilateral temporal lobe in TLE consumed more control
295 energy on average. Intuitively, the extra energetic demands in these patients may result in
296 suboptimal dynamics and inadequate activation, and eventually impair function. Additionally, by
297 conceptualizing TLE as a lateralized lesion model, we demonstrated that the imbalance of
298 energetic costs between the ipsilateral and contralateral mesial and inferior temporal regions was
299 also mirrored in their asymmetric metabolic patterns, whereby regions with lower baseline
300 metabolic levels also had higher energetic demands. Specifically, for the hippocampus, we found
301 significant associations between lateralization of energy costs, glucose uptake and gray matter
302 volume, with hypometabolism fully mediating the increase in energy demand pertaining to
303 volume loss on the ipsilateral side.
304   In this study, we focused on two main categories of brain state transitions. The first probed
305 the efficiency with which patients' brains could attain each of 8 ICN-defined preferential brain
306 states from a common baseline. Compared to HCs, TLE patients needed greater global control
307 energy to activate the limbic network, especially its ipsilateral side. Thus, it is plausible that
308 failing to meet these increased energy demands may underpin inadequate limbic activation and
309 dysfunction. Considering the overlap between the limbic network and the seizure focus in TLE,
310 dysfunction within this network is expected in these patients. For instance, episodic memory

15

311   deficits and affective comorbidities are commonly reported in TLE[11,13], and can be reasonably

312   attributed to limbic dysfunction. Previous imaging studies have shown that some limbic regions,

313   such as the epileptogenic hippocampus, are less activated during episodic memory encoding in

314   TLE[50–52]. Finally, altered functional connectivity seeded from the amygdala is also associated

315   with comorbid psychiatric symptoms in these patients[53]. In line with this evidence, our findings

316   suggest that TLE is associated with compromised energetic efficiency of ipsilateral limbic

317   regions.

318   Brain function depends on the ability to reach desired brain states and to swiftly transition

319   among them. Therefore, our second set of analyses focused on modeling the brain's capacity to

320   transition between pairs of ICN-defined preferential states. Across all possible pairwise

321   transitions, we found that TLE patients exhibited elevated control energy requirements compared

322   to HCs, again rooted in ipsilateral temporo-limbic regions. These results suggest that disruption

323   to the underlying structural networks of TLE patients not only affects the activation of the limbic

324   network, but also leads to greater energy demands of ipsilateral temporo-limbic regions during

325   transitions among all ICN-defined states. Finally, we sought to further validate our findings by

326   testing 100,000 pairs of random brain states that were not *a priori* rooted in functional

327   neuroanatomy. In doing so, we found near-identical results, demonstrating that the increased

328   energy costs in the ipsilateral temporo-limbic regions represent a general signature of

329   dysfunctional control of neuronal dynamics in TLE patients. Collectively, our study provides

330   evidence that altered brain dynamics in TLE, as a pathological trait, are underpinned by energetic

331   inefficiency that mostly affects areas in proximity or closely connected to the seizure focus, and

332   may represent a substrate of enduring brain dysfunction.

333   What is the neurophysiological basis of this trait? While NCT has been applied to

334   neuroscience in recent years, the biological nature of control energy has remained unclear. We

335   know that the brain consumes energy via glucose metabolism[6], and previous studies have linked

336   control energy to cognitive effort[25]. Therefore, we hypothesized that the magnitude of control

337   energy may reflect the extent of local metabolism needed to instantiate the desired neural

338   dynamics. Indeed, using FDG-PET, we showed that regional energetic inefficiency coexists with

339   altered metabolism in TLE. Considering unilateral TLE as a lesion model, we observed that

340   reduced baseline glucose intake (*i.e.*, hypometabolism) aligned, as clinically expected, with the

341   side of seizure focus. Taking the contralateral hemisphere as reference, we found that greater

342   ipsilateral hypometabolism was associated with greater ipsilateral energetic inefficiency. For the

343   first time, we thus highlight a formal link between theoretical control energy and a physiological

344   measure of brain metabolism, and suggest that the compromised metabolic baseline in affected

345   regions may lead to greater energetic challenges in supporting desired brain dynamics.

346   A common cause of metabolic alterations may be the loss of underlying structural integrity.

347   For instance, concomitant gray matter volume loss and hypometabolism is reported in patients

348   with TLE, especially in epileptogenic regions such as the hippocampus[54]. In our TLE patients,

349   we found that gray matter volume asymmetry was also associated with energy asymmetry in the

350   hippocampus. Through a mediation analysis, we formally demonstrated that the asymmetry of

16

351 baseline metabolism fully mediates the association between the asymmetry of gray matter
352 volume and energy costs. That is, greater volume loss may lead to greater baseline
353 hypometabolism, thereby increasing energy demands during brain state transitions in the
354 ipsilateral hippocampus. Such results deliver a unifying framework, linking independently
355 measured regional volumetrics, glucose metabolism, and network control properties derived
356 from structural networks. Our work thus captures both the metabolic and volumetric bases of
357 control energy, further supporting its application in modeling the endogenous resources
358 consumed during brain dynamics in the absence of external stimulation. In addition, our work
359 suggests that the magnitude of control energy is not only modulated by the transition
360 trajectory[25,29,37], but also by the integrity of the underlying structure. Specifically, regions
361 harboring pathology, such as the hippocampus in TLE, can exhibit different degrees of neural
362 loss, causing a metabolic resource gap that in turn impacts brain state transitions.
363   Several methodological considerations are pertinent to this study. First, the structural
364 connectome obtained via diffusion tractography used in our study is an approximation of the real
365 structural scaffold of functional brain dynamics. Implementing other forms of structural
366 connectivity, such as a spatial adjacency network, may provide added value to our model[37].
367 Second, we modeled the neural dynamics under assumptions of linearity and time-invariance,
368 following previous studies[26,29,36,37,40]. Recent research has shown that such simplified models can
369 provide useful first-order approximations of brain dynamics[55,56], and even outperform non-linear
370 models when predicting the macroscopic brain activity measured by functional magnetic
371 resonance imaging and intracranial electrocorticography[57]. Nonetheless, further adaptations are
372 expected to incorporate advanced features such as non-linearity[58,59] and time-dependence[60].
373 Third, as in previous studies[26,36,40], we defined a discrete set of brain states based on ICNs known
374 to underpin cognition[32,34,35]. Alternatively, the magnitude of brain states could also be defined
375 via empirically measured neurophysiological signals[25,27,29]. However, the estimated energy costs
376 in our model not only depend on the network structure, but also on the distance between the
377 initial and final states[29]. Thus, by setting binary states uniformly, we ensured a consistent
378 transition distance across all subjects. Accordingly, the extent of energy costs only reflects the
379 efficiency of the underlying network structure (or the lack thereof) during the same designated
380 dynamic process. Fourth, our TLE cohort was heterogeneous in etiology, which may raise the
381 possibility of subgroup-specific energetic characteristics that were not addressed in the current
382 study. Last, some antiepileptic drugs (AED) may affect brain dynamics[61]; however, due to the
383 heterogeneous regimen of AED history in our patients, we did not focus on the relationship
384 between AED and control energy profiles here. Similarly, while interictal epileptic discharges
385 (IEDs) can transiently influence brain dynamics, their relevance to control energy warrants
386 further investigation, as quantitative measures of IEDs were not available in this study.

Outlook

388   Focusing on temporal lobe epilepsy as a disease model, our study provides a framework
389 linking loss of structural integrity, alteration of local metabolism, and greater energetic
390 challenges to attain desired brain state transitions, leading to altered brain dynamics. By

17

391   providing a neurophysiological basis of control energy, our work paves the way for further

392   applications of network control theory in the field of neuroscience.

393   ## Methods

394   ### *Participants*

395   Sixty patients with refractory unilateral TLE (38 left-sided, 22 right-sided) were recruited

396   from the Thomas Jefferson Comprehensive Epilepsy Center. Diagnosis was determined by a

397   multimodal evaluation including neurological history and examination, interictal and ictal scalp

398   video-EEG, MRI, FDG-PET, and neuropsychological testing. Localization was determined after

399   confirming that the testing was concordant for unilateral temporal lobe epilepsy, as described

400   previously[62]. Patients were excluded from the study for any of the following reasons: previous

401   brain surgery, evidence for extra-temporal or multifocal epilepsy by history or testing,

402   contraindications to MRI, or hospitalization for any Axis I disorder listed in the DSM-5

403   (Diagnostic and Statistical Manual of Mental Disorders, V). Depressive disorders were

404   admissible, given the high comorbidity of depression and epilepsy[63]. The demographic and

405   clinical characteristics of the patient groups are presented in *Table 1*, along with the

406   demographic information of 50 age-, sex-, handedness-, and education-matched healthy controls

407   (HCs). All HC were free of psychiatric or neurological disorders based on a health screening

408   measure. This study was approved by the Institutional Review Board for Research with Human

409   Subjects at Thomas Jefferson University. All participants provided informed consent in writing.

410   ### *Imaging Acquisition*

411   All participants were scanned on a 3-T X-series Philips Achieva clinical MRI scanner

412   (Amsterdam, the Netherlands) at Thomas Jefferson University Hospital. The data acquisition

413   session included both a High Angular Resolution Diffusion Imaging (HARDI) scan as well as a

414   high-resolution T1-weighted (T1w) anatomical scan. The HARDI scan was 61-directional with a

415   b-value of 3000 s/mm^2 and TE/TR = 7517/98 ms, in addition to 1 b0 images. Matrix size was

416   96×96 with a slice number of 52. Field of view was 230×230 mm and slice thickness was

417   2.5 mm. Participants lay in a foam pad to comfortably stabilize the head, and were instructed to

418   remain still throughout the scan. Prior to collection of the HARDI scan, T1w images (180 slices)

419   were collected using an MPRage sequence (256×256 isotropic 1mm voxels; TR = 640 ms, TE =

420   3.2 ms, flip angle = 8°, FOV = 256×256 mm) in identical positions to provide an anatomical

421   reference. The in-plane resolution for each T1 slice was 1 mm^3 (axial oblique).

422   As part of their presurgical evaluation, 50 patients also underwent on-site PET scans. The

423   other 10 patients who received PET scans from other facilities (off-site), and HC who did not

424   receive PET scans, were excluded from the FDG-PET related analysis. All PET scans were

425   performed during interictal periods using a standard protocol. Pre-injection blood glucose level

426   was below 150 mg/dl for all patients (range: 61–128 mg/dl). An intravenous catheter was

427   inserted under local anesthesia and a dose around 5.9 ± 1.4 mCi of radioactive 100mg/l

428   fluorodeoxyglucose (FDG) was injected. The scan was initiated about 42 ± 15 min after the

429   injection. Participants' eyes were open, and their ears were non-occluded. Ambient noise and

18

430   light was kept to a minimum. Thirty-one patients (62% of patients; 20 LTLE, 11 RTLE) were

431   scanned on a Siemens Biograph 1080 PET/CT, with data consisting of 109 axial slices, 3 mm

432   thick, and 1×1 mm in resolution. The remaining 19 patients (38% of patients; 15 LTLE, 4

433   RTLE) were scanned on a Siemens Biograph 20 mCT PET/CT, with data consisting of 110 axial

434   slices, 3 mm thick, and 1.6×1.6 mm in resolution. Attenuation-corrected PET images were

435   iteratively reconstructed by standard vendor-provided software. There was no significant

436   difference in proportion of left and right TLE patients acquired with either scanner ($\chi^2 = 1.17$, p

437   = 0.28). Furthermore, we obtained asymmetry indices that use the same subject as reference,

438   therefore reducing potential scanner-specific bias, as reported previously[64]. This procedure also

439   avoids confounds related to demographic factors, such as age, medication history, and epilepsy

440   history[65,66]. Nevertheless, the scanner model was also used as a categorical nuisance regressor

441   during the data analysis along with demographic information.

Imaging Processing

443   The T1w and HARDI data were analyzed through QSIprep[67] (v0.8.0，

444   https://qsiprep.readthedocs.io), which is based on Nipype 1.4.2. QSIprep automates diffusion

445   MRI data preprocessing and reconstruction using well-recognized neuroimaging tools including

446   Advanced Normalization Tools (ANTs), Analysis of Functional NeuroImages (AFNI), FMRIB

447   Software Library (FSL), DSI Studio[68], MRtrix 3[69], and fMRIprep[70].

Anatomical data preprocessing

449   The T1w image was corrected for intensity non-uniformity using N4BiasFieldCorrection

450   (ANTs 2.3.1[71]), and was used as a T1w-reference throughout the workflow. The T1w-reference

451   was then skull-stripped using antsBrainExtraction.sh (ANTs 2.3.1), using OASIS as the target

452   template. Spatial normalization to the ICBM 152 Nonlinear Asymmetrical template version

453   2009c was performed through nonlinear registration with antsRegistration (ANTs 2.3.1[72]), using

454   brain-extracted versions of both T1w volume and template. Brain tissue segmentation of

455   cerebrospinal fluid (CSF), white-matter (WM) and gray-matter (GM) was performed on the

456   brain-extracted T1w using FAST (FSL 6.0.3[73]).

Diffusion data preprocessing

458   The HARDI image was first denoised using a Marchenko-Pastur principal component

459   analysis (MP-PCA) method[74], then underwent Gibbs-ringing artifacts removal[75], and then was

460   spatially bias corrected through MRtrix 3. Subsequently, it was corrected for head motion and

461   eddy current distortions via eddy_openmp (FSL 6.0.3). A deformation field to correct for

462   susceptibility distortions was estimated based on fMRIprep's fieldmap-less approach. The

463   deformation field was that resulting from co-registering the b0 reference to the same-subject

464   T1w-reference with its intensity inverted[76]. Registration was performed with antsRegistration

465   (ANTs 2.3.1), and the process was regularized by constraining the deformation to be nonzero

466   only along the phase-encoding direction, and was further modulated with an average fieldmap

467   template[77]. Based on the estimated susceptibility distortion, an unwarped b=0 reference was

468   calculated for a more accurate co-registration with the T1w-reference, and then a final

469   preprocessed HARDI image was produced in the native space of the T1w-reference with an

470   isotropic voxel size of 2 mm^3. Two quality metrics were calculated based on the preprocessed

471   data, including framewise displacement[78] and neighboring correlation[79].

472   *Diffusion data reconstruction and tractography*

473   The preprocessed HARDI image was reconstructed via MRtrix 3. Multi-tissue fiber response

474   functions were estimated using the Dhollander algorithm, during which Fibre Orientation

475   Distributions (FODs) were estimated via constrained spherical deconvolution [CSD[80,81]] using an

476   unsupervised multi-tissue method[82,83]. Specifically, a single-shell-optimized multi-tissue CSD

477   was performed using MRtrix3Tissue (https://3Tissue.github.io), a fork of MRtrix3. FODs were

478   intensity-normalized using mtnormalize[84]. Subsequently, an anatomically-constrained

479   probabilistic tractography[85] was performed using the iFOD2 probabilistic tracking method, in

480   which the WM FODs were used for tractography and the T1w segmentation was used for

481   anatomical constraints. For each subject we generated 10^7 streamlines with a maximum length of

482   250 mm, minimum length of 30 mm, and FOD power of 0.33. Weights for each streamline were

483   calculated using a spherical-deconvolution informed filtering of tractograms (SIFT2)[86], which

484   was then used to estimate the structural connectivity matrix.

485   *Brain parcellation customization*

486   Consistent with previous work[36], we chose the Lausanne parcellation scheme including n =

487   129 cortical and subcortical parcels[87] to build the structural network. This parcellation scheme is

488   established by sub-dividing the Desikan-Killiany anatomical atlas[88]. Specifically, to enable the

489   proposed asymmetry analysis, we needed the parcellation to be symmetric. However, we noted

490   that 6 regions have been subdivided asymmetrically, whereas the medial orbito-frontal gyrus,

491   inferior parietal gyrus, and lateral occipital gyrus have one more subdivision in the right

492   hemisphere, and the rostral middle frontal gyrus, precentral gyrus, postcentral gyrus have one

493   more subdivision in the left hemisphere. These additional subdivisions were subsequently

494   merged with their corresponding neighbor to match their cross-hemisphere counterpart,

495   producing a symmetric version of the parcellation constituted by 61 pairs of cortical and

496   subcortical parcels (excluding brainstem; details in **_Supplementary Table 2_**). This parcellation

497   was then inversely warped onto the native space of the T1w-reference and resampled at 2 mm^3

498   voxel resolution. Using tck2connectome (MRTrix3) allowing a 2 mm radial search from each

499   streamline endpoint to locate the nearest node, we built a 122 × 122 undirected adjacency matrix

500   for each subject with the SIFT2 weighted streamline counts representing interregional structural

501   connectivity.

502   To define neurobiologically meaningful brain states, we capitalized on an established

503   functional brain parcellation[89] of intrinsic connectivity networks (ICNs), which was defined by

504   clustering the resting-state functional connectivity data from 1000 healthy subjects[33]. This

505   parcellation is constituted by 7 cortical ICNs that are commonly seen during both resting and

506   task conditions[32,34], including visual (VIS), somatomotor (SM), dorsal attention (DAN),

507   salience/ventral attention (SAL/VAN), limbic (LIM), executive control (CONT), and default

508   mode networks (DMN). As in prior work[36], we mapped both parcellations to a common surface

509   space (fsaverage), and calculated the proportional overlap of vertices between each parcel and

510　each of the 7 ICNs. Using a winner-take-all strategy, we assigned each parcel to the ICN with

511　highest overlap proportion (**Figure 1b**). In addition, subcortical regions were summarized in an

512　eighth, subcortical network (SC), excepting for the hippocampus and amygdala, which were

513　assigned to the limbic network following the common clinical definition[14]. These 8 non-

514　overlapping networks were used as representative brain states during simulations of brain state

515　transitions.

516　*FDG-PET data preprocessing*

517　　　PET images were preprocessed with Statistical Parametric Mapping 12 (SPM 12,

518　http://www.fil.ion.ucl.ac.uk/spm/software/spm12), as in previous work[90]. Briefly, the PET image

519　was first co-registered to the T1w-reference image, smoothed with a 6-mm kernel, and intensity-

520　normalized by the global mean uptake estimated based on a skull-striped brain mask derived

521　from the T1w-reference image. Regional mean glucose uptake was subsequently estimated based

522　on the same parcellation. As stated, in the absence of PET data from HC, we calculated the

523　laterality index (LI, $LI_i = \frac{L_i - R_i}{L_i + R_i}$) of regional glucose uptake from the aforementioned 61 pairs of

524　parcels for the subsequent analyses.

525　*Regional gray matter volume estimation*

526　　　Lastly, we obtained regional mean gray matter volumes (GMV) using the Computational

527　Anatomy Toolbox (CAT12, v12.7, http://www.neuro.uni-jena.de/cat/). The T1w image was first

528　denoised with a spatial adaptive non-local means (SANLM) denoising filter[91], followed by

529　internal resampling to properly accommodate low-resolution images and anisotropic spatial

530　resolutions. Subsequently, the data was bias-corrected and affine-registered followed by the

531　standard SPM "unified segmentation"[92]. The brain was then parcellated into left and right

532　hemispheres, subcortical areas, and the cerebellum. Furthermore, local white matter

533　hyperintensities were detected to be later accounted for during the spatial normalization.

534　Subsequently, a local intensity transformation of all tissue classes was performed, and a final

535　adaptive maximum *a posteriori* (AMAP) segmentation[93] was then refined by applying a partial

536　volume estimation[94], which effectively estimated the fractional content for each tissue type per

537　voxel. Last, the tissue segments were spatially normalized to a common reference space using

538　Geodesic Shooting[95] registration, so that the regional GMV could be estimated based on the

539　same parcellation. In addition, the total intracranial volume and a summary image quality rating

540　for each T1w image were exported, and were used as covariates.

541　***Brain State Transitions Simulated through Linear Network Control Theory***

542　*Theoretical framework of Linear Network Control Theory*

543　　　To investigate whether TLE is associated with compromised efficiency of common brain

544　dynamics, we leveraged recent developments of linear network control theory, and explored the

545　energetic efficiency of the structural brain network in facilitating designated brain state

546　transitions. As in previous work[26,29,36,37,40], we employed a simplified noise-free linear and time-

547　invariant network model to describe the dynamics of the brain:

548
$$\dot{x} = Ax(t) + Bu(t).$$

21

549   (1)

550 Here, $x(t)$ is a N × 1 vector that represents the state (*i.e.*, activity level) of each node of the

551 system at time t (N = 122). A is a N × N adjacency matrix denoting the relationship between the

552 system elements, which can be operationalized as the structural brain network. To ensure the

553 stability of the system, A is normalized as follows[37]:

$$A_{norm} = \frac{A}{\|\lambda(A)_{max}\| + 1} - I,$$

555

554   (2)

556 whereas $\lambda(A)_{max}$ denotes the largest positive eigenvalue of the system and I denotes the N × N

557 identity matrix. B is the input matrix that identifies the nodes in the control set. Here we set B to

558 be the N × N identity matrix to set all the brain parcels as control nodes where energy can be

559 consumed to facilitate brain state transitions. Last, $u(t)$ denotes the amount of energy injected

560 into each control node at each time point t. Intuitively, $u(t)$ can be summarized over time to

561 represent the total energy consumption during transition from an initial state to a final state.

562 *Simulation I: Individual ICN activation*

563   In our first simulation, we considered the scenario that the brain transits from an initial

564 baseline state ($x_0 = x(t = 0)$) to a final state ($x_T = x(t = T)$) when a specific ICN is

565 predominantly activated. We modeled this control task by setting:

$$x_i(t = 0) = 0, i = 1, \dots, 122,$$

566

567 and

$$x_i(t = T) = \begin{cases} 0, & if\ i \notin ICN_k \\ 1, & if\ i \in ICN_k \end{cases}, k = 1, \dots, 8.$$

568

569 Note that, theoretically, setting the initial state to full zeros does not necessarily mean that the

570 brain is globally inactive, which is biologically impossible. Rather, it can be viewed as a mean-

571 centered baseline, and the final state has additional activations within the specific ICN than other

572 regions by 1 arbitrary unit. This setting is analogous to task fMRI analyses, where contrasts are

573 commonly set between a condition of interest (1) and a baseline (0)[26].

574   To explore the energetic efficiency of the structural brain network in facilitating the

575 activation of specific ICNs, we adopted the optimal control framework to estimate the control

576 energy required to optimally steer the brain through these state transitions[26,29]. Against a

577 naturalistic trajectory, when the brain state drifts without any control input, the proposed state

578 transition commonly relies on the additional control input $u(t)$ to reach the desired final state.

579 This control effort can be intuitively understood as an internal cognitive control process (or as

580 external brain stimulation in other patient scenarios), and it is based on both the energy costs and

581 the length of the transition trajectory[37]. Therefore, an optimal solution can be described as the

582 minimized combination of both the length of the transition trajectory and the required control

583 energy, during the state transition from an initial state ($x(0) = x_0$) to the final state ($x(T) =$

584 x_T) over the time horizon T (see Refs. [40,96]):

$$u(t)^* = \operatorname*{argmin}_{u} J(u) = \operatorname*{argmin}_{u} \int_0^T \left((x_T - x(t))^\top S (x_T - x(t)) + \rho u(t)^\top u(t) \right) dt,$$

585

586   (3)

587   where $(x_T - x(t))^\top (x_T - x(t))$ is the distance between the state at time t and the final state x_T,

588   T is the finite amount of time given to reach the final state, and ρ is the relative weighting

589   between the cost associated with the length of the transition trajectory and the input control

590   energy. Following a previous benchmarking study[37], we set $T = 3$ and $\rho = 1$, allowing 1000

591   steps of transition from the initial state to the final state. To minimize the unintended energy cost

592   on regulating the regions of no interest (*i.e.*, those outside of the target ICN), we applied a

593   constraint matrix S, which is a N × N binary diagonal matrix that selects only regions that are

594   members of the target ICN. Accordingly, the term $(x_T - x(t))^\top S(x_T - x(t))$ specifically

595   constrains the trajectories of all regions within the target ICN, and the term $u(t)^\top u(t)$ constrains

596   the amount of control energy used to reach the final state. The cost function $J(u(t)^*)$ is used to

597   solve the unique optimal control input $u(t)^*$. Specifically, we define a Hamiltonian as:

599 $$H(p, x, u, t) = (x_T - x)^\top S(x_T - x) + \rho u^\top u + p(Ax + Bu).$$

598   (4)

600   According to the Pontryagin minimization principle[96], if u^* is a solution with the optimal

601   trajectory x^*, then there exists a p^* such that:

603 $$\frac{\partial H}{\partial x} = -2S(x_T - x^*) + A^\top p^* = -\dot{p}^*,$$

604 $$\frac{\partial H}{\partial p} = Ax^* + Bu,$$

605 $$\frac{\partial H}{\partial u} = 2\rho u^* + B^\top p^* = 0.$$

602   (5)

606   From this set of equations, we can derive that:

608 $$u^* = -\frac{1}{2\rho} B^\top p^*,$$

607   (6)

609 $$\dot{x}^* = Ax^* - \frac{1}{2\rho} BB^\top p^*,$$

610   (7)

611   which can be reduced to:

613 $$\begin{bmatrix} \dot{x}^* \\ \dot{p}^* \end{bmatrix} = \begin{bmatrix} A & -\frac{1}{2\rho} BB^\top \\ -2S & -A^\top \end{bmatrix} \begin{bmatrix} x^* \\ p^* \end{bmatrix} + \begin{bmatrix} 0 \\ 2S \end{bmatrix} x_T.$$

612   (8)

614   If we denote:

615 $$\tilde{A} = \begin{bmatrix} A & -\frac{1}{2\rho} BB^\top \\ -2S & -A^\top \end{bmatrix},$$

23

616
$$\tilde{x} = \begin{bmatrix} x^* \\ p^* \end{bmatrix},$$

617
$$\tilde{b} = \begin{bmatrix} 0 \\ 2S \end{bmatrix} x_T,$$

618 then this reduced equation (8) can be rewritten as:

619
$$\dot{\tilde{x}} = \tilde{A}\tilde{x} + \tilde{b},$$

620 and can be solved as:

622
$$\tilde{x}(t) = e^{\tilde{A}t}\tilde{x}(0) + \tilde{A}^{-1}(e^{\tilde{A}t} - I)\tilde{b}.$$

621
$$(9)$$

623 Then, by fixing $t = T$, we arrive at:

625
$$\tilde{x}(T) = e^{\tilde{A}T}\tilde{x}(0) + \tilde{A}^{-1}(e^{\tilde{A}T} - I)\tilde{b}.$$

624
$$(10)$$

626 We let:

627
$$c = \tilde{A}^{-1}(e^{\tilde{A}T} - I)\tilde{b},$$

628
$$e^{\tilde{A}T} = \begin{bmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{bmatrix},$$

629 so that equation (10) can be rewritten as:

631
$$\begin{bmatrix} x^*(T) \\ p^*(T) \end{bmatrix} = \begin{bmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{bmatrix} \begin{bmatrix} x^*(0) \\ p^*(0) \end{bmatrix} + \begin{bmatrix} c_1 \\ c_2 \end{bmatrix},$$

630 from which we can obtain:

633
$$x^*(T) = E_{11}x^*(0) + E_{12}p^*(0) + c_1.$$

632
$$(11)$$

634 Moreover, if we let $\bar{S} = I - S$, then as a known result in optimal control theory[24], $\bar{S}p^*(T) = 0$.
635 Therefore,

637
$$\bar{S}p^*(T) = \bar{S}E_{21}x^*(0) + \bar{S}E_{22}p^* + \bar{S}c_2 = 0.$$

636
$$(12)$$

638 Finally, $p^*(0)$ can be solved for as follows:

640
$$p^*(0) = \begin{bmatrix} SE_{12} \\ \bar{S}E_{22} \end{bmatrix}^+ \left(-\begin{bmatrix} SE_{11} \\ \bar{S}E_{21} \end{bmatrix} x^*(0) - \begin{bmatrix} Sc_1 \\ \bar{S}c_2 \end{bmatrix} + \begin{bmatrix} Sx(T) \\ 0 \end{bmatrix} \right),$$

639
$$(13)$$

641 where $[\cdot]^+$ indicates the Moore-Penrose pseudoinverse of a matrix. Now that we have obtained
642 $p^*(0)$, we can use it and $x(0)$ to solve for $\tilde{x}$ via forward integration based on equation (9). To
643 solve for u^*, we take p^* from our solution for $\tilde{x}$ and solve equation (6). In particular, the optimal
644 control energy injected at each region i can be defined as:

646
$$E_i^* = \int_0^T \|u_i^*(t)\|^2 dt,$$

645
$$(14)$$

647 or given in total:

648
$$E_{opt}^* = \sum_{i=1}^m E_i^* = \int_0^T u^*(t)^\top u^*(t) dt.$$

24

649   (15)

650   This total optimal control energy consumption E_{opt}^* is then used as a measure of efficiency of the

651   structural brain network during specific ICN activations.

652   *Simulation IIa: Between ICN transitions*

653   In our second simulation, we investigated the regional energetic consumption associated with

654   facilitating brain dynamics. While it is computationally impossible to simulate all brain

655   transitions, we considered two sets of finite repositories instead. First, we used the 8 ICN-defined

656   representative brain states (*i.e.*, the x_T in *Simulation I*), and explored all the possible transitions

657   among them[36]. Counting scenarios of both reciprocal transitions and single state persistence (*i.e.*,

658      $x_0 = x_T$), this simulation resulted in a total of 64 control tasks. Considering the linear nature of

659   our dynamical model, theoretically any possible transition can be written as a linear combination

660   of the proposed transitions[36]. Thus, this simulation is generally relevant to all transitions

661   represented during common brain dynamics.

662   We further alleviated the constraint on the length of the transition trajectory in our model, to

663   allow the brain to travel more freely across different intermediate states. Specifically, we adopted

664   a subform of the optimal control framework, namely the minimal control energy, which can be

665   obtained by letting $\rho \to \infty$ in equation (3), so that the cost function J accounts only for the

666   control input to facilitate the designated transition regardless of the trajectory[37]. Accordingly, the

667   minimal control energy during the state transition from an initial state ($x(0) = x_0$) to the final

668   state ($x(T) = x_T$) over the time horizon T can be described as[4,27,37]:

670
$$u(t)^* = \operatorname*{argmin}_u J(u) = \operatorname*{argmin}_u \int_0^T u(t)^\mathsf{T} u(t)\, dt.$$

669   (16)

671   To solve the minimal control energy $u(t)^*$ this time, we compute the controllability Gramian W

672   for controlling the network A from the control node set B in equation (1) as:

674
$$W = \int_0^T e^{A(T-t)} B B^\mathsf{T} e^{A^\mathsf{T}(T-t)} dt,$$

673   (17)

675   where, as defined previously, A is the normalized N × N structural brain network, B is a N × N

676   identity matrix setting all the brain parcels as control nodes, and T is the finite time horizon of

677   the transition trajectory. Similarly, we set $T = 3$ and allow for 1000 steps of transition from the

678   initial state to the final state following Ref.[37]. Then, the $u(t)^*$ can be computed as:

680
$$u(t)^* = B^\mathsf{T} e^{A^\mathsf{T}(T-t)} W^{-1} \big(x(T) - e^{AT} x(0) \big),$$

679   (18)

681   and the minimal control energy injected at each region i can calculated based on equation (14).

682   Finally, for each brain region, we averaged their minimal control energy across the 64 control

683   tasks as a measure of their individual energetic consumption during dynamics among known

684   ICNs.

685 *Simulation IIb: Random brain state transitions*

686   The second set of finite repositories of brain states included 100,000 pairs of randomly

687 generated initial and final brain states x_{rand} with a Gaussian distribution at $mean(x_{rand}) = 1$

688 and $std(x_{rand}) = 0.1$[26]. Accordingly, this simulation resulted in a total of 100,000 control tasks,

689 which served as an approximation of all transitions when no prior preference of brain states is

690 explicitly defined. Based on our previous argument of the linear nature of the model, we were

691 not expecting significant difference between our previous *Simulation IIa* and this *Simulation IIb*.

692 Rather, we expected to observe a consistency between the two, which would serve as a

693 validation of *Simulation IIa*. Similarly, we adopted the same minimal control framework, and for

694 each brain region, we calculated and summarized their minimal control energy across the

695 100,000 control tasks as the measure of their individual energetic consumption during brain

696 dynamics among randomly organized brain networks.

697 ### Statistical Inferences

698   Comparisons for common demographic and clinical information were made with standard

699 parametric tests such as an independent *t*-test or Chi-Square test, conducted using IBM® SPSS®

700 v25. The alpha level was set at $P < 0.05$ for both parametric and nonparametric tests.

701 *Confounding factor regression*

702   To minimize the influence of individual variances of the demographic characteristics and

703 imaging data qualities (**Table 1**), confounding factor regressions were applied before statistical

704 inferences on our neuroimaging data. Specifically, for derivates from all imaging modalities, 4

705 potential confounding factors were identified and included in the models: age, sex, handedness,

706 and total intracranial volume. Furthermore, additional confounding factors were added to the

707 models for different modalities: (i) for HARDI derivates (*i.e.*, control energy), the neighboring

708 correlation, mean framewise displacement, matrix density, and total weight were added; (ii) for

709 T1w derivates (*i.e.*, regional gray matter volume), the image quality rating was added; (iii) for

710 FDG-PET derivates (*i.e.*, regional glucose uptake), the PET scanner model was added. For each

711 modality, all confounding factors were regressed out from their derivates with one linear

712 regression model, and the residuals were taken for subsequent statistical analyses.

713 *Permutation-based Nonparametric Statistical Testing*

714   To minimize the bias of the data distribution to our statistical inference and to correct for

715 multiple comparisons, we implemented a permutation-based method as our main statistical

716 strategy[41]. Individual permutation-based statistical testing allows inference of the probability of

717 the observed statistic (*e.g.*, *t*-value), from a distribution of the same statistic estimated from

718 massive instances of the same samples with their group identities permuted[97]. In many cases, we

719 wish to apply a permutation-based test to scenarios with multiple comparisons, *i.e.*, comparing

720 multiple within-subject variables across the same groups of subjects. In this case, we can expand

721 the traditional approach by applying a "t_{max}" principle to adjust the estimated *P*-values of each

722 variable for multiple comparisons by controlling the family-wise error rate[42]. Briefly, the

723 observed statistic for each variable is compared to the distribution of the most extreme statistic

724 across the entire family of tests for each possible permutation. This procedure corrects for

26

725   multiple comparisons, because the distribution of the most extreme statistics automatically

726   adjusts to reflect the increased chance of false discoveries due to an increased number of

727   comparisons[41]. We performed 1,000,000 permutations each time to ensure high precision during

728   *P*-value estimation[44]. This strategy was applied on all analyses (*i.e.*, *t*-tests, product-moment

729   correlation) when multiple comparison correction was required.

730   To increase statistical power[38,43,44], the regional control energy values of the right TLE

731   patients were flipped left to right, allowing all statistical analyses to be conducted in accordance

732   with the site of ictal onset (left, ipsilateral; right, contralateral). However, as there was no way to

733   flip HC data to match the ipsilateral versus contralateral side in the right TLE patients, we

734   instead calculated the deviation score of regional energy [$Z_{pat} = (E_{pat} - \mu_{con})/\sigma_{con}$, where

735   μ_{con} and σ_{con} were the mean and standard deviation of the same regional energy from the HC]

736   for each patient at each hemisphere, and flipped the Z-score of right TLE afterwards[38,44,45]. Then,

737   Z-scores were evaluated via a permutation-based one-sample *t*-test.

738   *Permutation-based Mediation Analysis*

739   To disentangle the associations among regional gray matter volume change, glucose

740   metabolism and control energy consumption in the hippocampus, we applied a mediation

741   analysis to test the hypothesis that the regional metabolic baseline, as a measure of functional

742   integrity, mediates the relationship between local structural integrity and energetic efficiency.

743   After confound regression, we generated the laterality indices for gray matter volume, glucose

744   uptake, and minimal control energy estimated during cross-ICN transitions. We then evaluated

745   the significance of the indirect effect using bootstrapped confidence intervals via the

746   MediationToolbox[98]. Specifically, we examined: (i) path c: the total effect of the LI of gray

747   matter volume on the LI of minimal control energy; (ii) path a: the relationship between the LI of

748   gray matter volume and the LI of glucose uptake; (iii) path b: the relationship between the LI of

749   glucose uptake and the LI of minimal control energy; and (iv) path c': the direct effect of the LI

750   of gray matter volume on the LI of minimal control energy while controlling for the mediator (LI

751   of glucose uptake). The mediation/indirect effect a*b is the effect size of the relationship

752   between the LI of gray matter volume and the LI of minimal control energy that was reduced

753   after controlling for the mediator (LI of glucose uptake). For each path, we calculated the beta

754   coefficient, which reflected the changes of the outcome for every one-unit change in the

755   predictor. A bootstrap analysis (*i.e.*, resampled 1,000,000 times) was implemented to estimate

756   the confidence intervals for the indirect effect.

Figures Captions

987

988   **Figure 1. Schematic of methods.** (a) Based on a simplified noise-free, linear, continuous-time,
989   and time-invariant model of neural dynamics, we simulate energetic processes during brain state
990   transitions instantiated upon and constrained by the structural connectome (matrix A). Two types
991   of control energy (a quadratic function of u) are depicted: the minimum control energy required
992   to drive the brain from an initial state $[x(0)]$ to a final state $[x(T)]$ using a specific set of control

993   nodes (whole brain, matrix B); the optimal control energy additionally constrains the length of

994   the trajectory between states. (b) Eight preferential brain states are defined according to the

995   known intrinsic connectivity networks (ICN)[32,33]. Within each state, regions from a specific ICN

996   are activated at a magnitude of 1, whereas the rest of the brain remains at 0 (inactivated). These

997   preferential brain states constitute the initial and final states of our simulations. (c) We then

998   simulate the energetic inputs required to activate each of the preferential brain states from a

999   theoretical baseline (*i.e.*, activity magnitude of 0). Next, we estimate the optimal control energy

1000   consumed during each of the activation processes across the whole brain for each subject. (d) We

1001   also simulate transitions between preferential brain states, and estimate the minimal control

1002   energy consumed at each brain region for each subject. Abbreviations: VIS, visual network;

1003   SMN, somatomotor network; DAN, dorsal attention network; SAL/VAN, salience/ventral

1004   attention network; CONT, executive control network; DMN, default mode network; SUB,

1005   subcortical network.

1006   **Figure 2. Global optimal control energy (OCE) estimated during simulated activation of**

1007   **intrinsic connectivity networks.** After correction for multiple comparisons, significant group

1008   differences were only found for the simulated activation of the limbic network (LIM), which

1009   demanded more global OCE in patients with temporal lobe epilepsy (TLE) compared to healthy

1010   controls (HC). Other abbreviations: VIS, visual network; SMN, somatomotor network; DAN,

1011   dorsal attention network; SAL/VAN, salience/ventral attention network; CONT, executive

1012   control network; DMN, default mode network; SUB, subcortical network. **, $P_{corr} < 0.01$. The

1013   central mark indicates the median, and the bottom and top edges of the box indicate the 25th and

1014   75th percentiles, respectively.

1015   **Figure 3. Global optimal control energy (OCE) estimated during a simulated transition**

1016   **from the baseline to a final state where only one side of the limbic network (LIM) is**

1017   **activated.** When the target was set to the left hemispheric LIM, only left temporal lobe epilepsy

1018   patients (LTLE) needed more energy than the other two groups. When the target was set to the

1019   right hemispheric LIM, only right TLE patients (RTLE) needed more energy than the other two

1020   groups. Other abbreviations: HC, healthy controls. *, $P_{Bonferroni}<0.05$, **, $P_{Bonferroni}<0.01$, ***,

1021 $P_{Bonferroni}<0.001$. The central mark indicates the median, and the bottom and top edges of the box

1022   indicate the 25th and 75th percentiles, respectively.

1023   **Figure 4. Regional energy efficiency differences between temporal lobe epilepsy (TLE)**

1024   **patients and healthy controls (HC).** (a) We estimated the minimal control energy consumption

1025   of each region during all transitions between the brain states defined by intrinsic connectivity

1026   networks (ICNs). In the hemisphere ipsilateral to the seizure focus, we found significantly higher

1027   energy consumption in TLE patients than in HC among several temporo-limbic regions. (b) We

1028   then estimated the minimal control energy consumption of each region during transitions

1029   between 100,000 pairs of initial $[x(0)]$ and final states $[x(T)]$ with randomly generated activity

1030   magnitudes. Concordant results were found, showing that the patients needed significantly

1031   higher control energy in the ipsilateral temporo-limbic regions. The box plots depict the

1032   deviation scores (Z) of energy consumption of TLE patients in reference to HC. Only regions

1033   with significant group differences after multiple comparison corrections are displayed, including
1034   the isthmus of the cingulate gyrus (Isthmuscingulate-1), fusiform (Fusiform-2), temporal pole
1035   (Temporalpole-1), inferior temporal gyrus (Inferiortemporal-1), parahippocampal gyrus
1036   (Parahippocampal-1), amygdala, and hippocampus.

1037   **Figure 5. Regional control energy consumption is associated with glucose metabolism in**
1038   **temporal lobe epilepsy patients.** (a) Multiple comparisons corrected one sample *t*-tests on
1039   laterality indices (LI) of regional glucose uptake reveal widespread ipsilateral hypometabolism in
1040   reference to the metabolic levels in the contralateral hemisphere (upper panel). Notably, all the
1041   ipsilateral temporo-limbic regions with atypical energetic profiles also present with
1042   hypometabolism (lower panel). (b-h) Pearson correlations corrected for multiple comparisons
1043   revealed significant associations between the laterality of glucose uptake and minimal control
1044   energy consumption during all the transitions between the states defined by intrinsic connectivity
1045   networks (ICN), most prominently in the limbic regions, whereas the side with lower glucose
1046   metabolic baseline consumes more control energy. Corrected *P*-values (P_{corr}) are depicted. (i) A
1047   mediation analysis is performed on the hippocampus, where the association between the
1048   laterality of gray matter volume (LI-Vol) and control energy (LI-CE) is also found to be
1049   significant. We found that the laterality of glucose uptake (LI-Glu) provides a full mediation of
1050   the association between the former two variables. The significance of the mediation effect was
1051   assessed using bootstrapped confidence intervals.

1052   **Tables**

1053   **Table 1.** Sample demographic and clinical characteristics.

Experimental Group (N)	TLE (60)	HC (50)	T/χ^2	P
Age	41.13±14.41	37.98±11.78	1.24	0.218

FIAS/FAS	9
FIAS+FBTCS	22
FAS+FBTCS	1
FIAS/FAS+FBTCS	14
FBTCS	4
Num. of current AEDs (1/2/3)	27/26/7

1054 Continuous variables were presented as mean ± standard deviation. Abbreviations and
1055 definitions: TLE, patients with temporal lobe epilepsy; HC, healthy controls; HARDI, high
1056 angular resolution diffusion imaging; FIAS, focal impaired awareness seizure; FAS, focal aware
1057 seizure; FBTCS, focal to bilateral tonic-clonic seizure; AED, anti-epileptic drug. The quality of
1058 T1-weighted images was assessed with an image quality rating and the total intracranial volume
1059 produced with the Computational Anatomy Toolbox (CAT12)[99]. The quality of HARDI data was
1060 assessed with a neighboring correlation index[79] which quantified the similarity between low-b
1061 volumes with similar gradient directions, as well as with the mean framewise displacement[78] as a
1062 measure of head motion. Seizure focus was classified as: left temporal (LT) and right temporal
1063 (RT). Temporal pathology was diagnosed by neuroradiologists based on presurgical MRI scans
1064 as: normal brain MRI (NB); hippocampal sclerosis (HS); other pathologies (Other), such as
1065 tumor, focal cortical dysplasia, encephalocele, etc. FBTCS history was sorted as: *none*, patients
1066 who had never had any FBTCS events during their lifetime; *remote*, patients who had
1067 experienced FBTCS in the past, but none for one year or more prior to scanning; *current*,
1068 patients who had recurrent FBTCS within one year prior to scanning[44,100]. For continuous
1069 variables, independent *t*-tests were conducted. For categorical variables, chi-square tests were
1070 conducted. Significant differences were highlighted in bold.

Citation diversity statement

1072 Recent work in several fields of science has identified a bias in citation practices such that
1073 papers from women and other minority scholars are under-cited relative to the number of such
1074 papers in the field[1-9]. Here we sought to proactively consider choosing references that reflect the
1075 diversity of the field in thought, form of contribution, gender, race, ethnicity, and other factors.
1076 First, we obtained the predicted gender of the first and last author of each reference by using
1077 databases that store the probability of a first name being carried by a woman[5, 10]. By this measure
1078 (and excluding self-citations to the first and last authors of our current paper), our references
1079 contain 7.41% woman(first)/woman(last), 18.52% man/woman, 18.52% woman/man, and
1080 55.56% man/man. This method is limited in that a) names, pronouns, and social media profiles
1081 used to construct the databases may not, in every case, be indicative of gender identity and b) it
1082 cannot account for intersex, non-binary, or transgender people. Second, we obtained predicted

35

1083 racial/ethnic category of the first and last author of each reference by databases that store the

1084 probability of a first and last name being carried by an author of color[11, 12]. By this measure (and

1085 excluding self-citations), our references contain 9.79% author of color (first)/author of

1086 color(last), 12.4% white author/author of color, 25.2% author of color/white author, and 52.62%

1087 white author/white author. This method is limited in that a) names and Florida Voter Data to

1088 make the predictions may not be indicative of racial/ethnic identity, and b) it cannot account for

1089 Indigenous and mixed-race authors, or those who may face differential biases due to the

1090 ambiguous racialization or ethnicization of their names. We look forward to future work that

1091 could help us to better understand how to support equitable practices in science.

Acknowledgements

Author contributions

1143   X.H. and D.S.B. designed the study. X.H. performed all analyses and wrote the initial draft
1144 of the manuscript. L.C. and L.P. contributed to the drafting and revising of the manuscript. J.S.
1145 and T.M.K. contributed to the analytical code. J.Z.K., Z.L., T.M., and F.P. contributed analytic
1146 solutions. M.R.S. and J.I.T. provided the clinical and imaging data. All authors edited the
1147 manuscript and approved the final version.
