50

51   **Abstract**

52   Naked mole-rats (NMRs) have a very low spontaneous carcinogenesis rate, which has prompted
53   scientists to study their cancer resistance mechanisms in order to provide clues for human cancer
54   prevention. Although cancer resistance in NMRs has been intensively investigated at the cellular
55   level, it is still unknown how strongly resistant NMR individuals are to carcinogenesis and how
56   NMR tissues respond to experimental carcinogenesis induction. Here, we show that NMRs
57   exhibit extraordinary resistance against potent chemical carcinogenesis induction through a
58   dampened inflammatory response. Although carcinogenic insults damaged skin cells of both
59   NMRs and mice, NMR skin showed markedly lower immune cell infiltration and reduced induction
60   of inflammatory genes. NMRs harbor loss-of-function mutations in receptor-interacting protein
61   kinase 3 (*RIPK3*) and mixed lineage kinase domain-like (*MLKL*) genes, which are essential for
62   necroptosis, a type of necrotic cell death that activates strong inflammation. A necroptosis-
63   inducing stimulus did not increase death of NMR cells. After carcinogenic insults, leakage of the
64   HMGB1, a marker of necrotic cell death, was not increased in NMR skin. In mice, inhibition or
65   knockout of RIPK3 reduced immune cell infiltration and delayed the onset of chemical
66   carcinogenesis. Therefore, necroptosis deficiency may serve as a cancer resistance mechanism
67   via attenuating the inflammatory response in NMRs. Our study sheds light on the importance of a
68   dampened inflammatory response as a non-cell-autonomous cancer resistance mechanism in
69   NMRs. Further in vivo study of the unusual tissue immune system and carcinogenesis resistance
70   of NMRs may lead to the development of new strategies to prevent carcinogenesis in humans.

71   **Significance Statement**

72
73   In contrast with intensive studies of cancer resistance mechanisms in naked mole-rats (NMRs) at
74   the cellular level, little is known about how NMR individuals respond to carcinogenesis induction,
75   despite the fact that cell-to-cell interactions in tissues regulate carcinogenesis in vivo. Here, we
76   demonstrate that NMRs are remarkably resistant to chemical carcinogenesis induction and
77   characteristically have attenuated tissue inflammatory responses to carcinogenic insults. NMRs
78   have loss-of-function mutations in *RIPK3* and *MLKL* genes and thus cannot activate necroptosis,
79   a type of inflammation-inducing cell death. RIPK3 inhibition in mice reduced immune cell
80   infiltration in response to carcinogenic insults and delayed the onset of chemical-induced

81   carcinogenesis. Our results highlight the importance of studies on dampened tissue inflammatory
82   responses to understand cancer resistance of NMRs.
83

85
86   **Introduction**
87
88   The naked mole-rat (NMR) is the longest-living rodent with a maximum lifespan of 37 years,
89   despite being comparable size to the laboratory mice, and previous studies have reported that it
90   is protected from age-associated declines in biological functions and aging-related disorders (1,
91   2). In particular, spontaneous carcinogenesis has rarely been observed in over 2,000 necropsies
92   of captive NMR colonies (3, 4). This provides clear evidence of the cancer resistance properties
93   of NMRs; however, to the best of our knowledge, it is the only evidence to date of their cancer
94   resistance in vivo. On the other hand, several recent reports demonstrated that some NMRs
95   spontaneously develop cancers (5–7). Therefore, it is unclear how strongly resistant NMR
96   individuals are to carcinogenesis. Moreover, there is no report regarding the tissue response of
97   NMRs to experimental induction of carcinogenesis in vivo.
98   Intracellular mechanisms that may contribute to cancer resistance in NMRs have been
99   proposed (8–10); however, whether NMR cells have strong cell-autonomous cancer resistance is
100   currently debatable. There are two reports that NMR cells, in contrast to mouse cells, do not
101   transform upon introduction of HRasV12 and SV40 Large T antigen (9, 11), and conversely
102   another report involving extensive experiments that they do (12). One limitation of previous
103   studies is that the findings are based on in vitro experimental transformation of cultured
104   fibroblasts and their xenografts in immunodeficient mice.
105   In vivo carcinogenesis includes an initiation stage, in which DNA damage results in the
106   generation of mutant cells. This is followed by changes in the tissue microenvironment around the
107   mutant cells, which comprises surrounding immune cells and stromal cells. Microenvironmental
108   changes regulate various environmental factors and promote carcinogenesis in a promotion stage
109   (13, 14). In particular, tissue inflammation induces further genetic and epigenetic alterations of
110   mutant cells and strongly promotes carcinogenesis in a non-cell-autonomous manner (15–18).
111   Therefore, previous studies on the cancer resistance of cultured NMR fibroblasts might pay little
112   attention to the physiological context of in vivo carcinogenesis and might overlook relevant cancer
113   resistance mechanisms in NMR tissues.
114   Here, we show that NMR individuals exhibit extraordinary resistance to carcinogenesis
115   induction by chemical carcinogens in vivo. Notably, NMR skin tissues showed an unusual
116   dampened inflammatory response to carcinogenic insults. NMRs harbor loss-of-function
117   mutations in receptor-interacting protein kinase 3 (*RIPK3*) and mixed lineage kinase domain-like
118   (*MLKL*), the regulators of necroptosis, a type of strong inflammation-activating cell death
119   associated with various inflammatory diseases (19). Loss of necroptosis-inducing ability in NMRs
120   may serve as a mechanism that attenuates inflammatory responses and suppresses
121   carcinogenesis in vivo. This study highlights a dampened tissue inflammatory response as a non-
122   cell-autonomous mechanism underlying carcinogenesis resistance in NMR individuals.
123
124   **Results**
125
126   **NMRs show marked resistance to chemical carcinogenesis induction**
127
128   The in vivo responses of NMR tissues to carcinogenic insults were examined using two types of
129   chemical carcinogens, and the effects were compared with those in mice. First, mice and NMRs
130   received intramuscular injections of 3-methylcholanthrene (3MC), a carcinogen in various rodent
131   species (20–22) (Fig. 1A). After treatment, all mice developed fibrosarcomas within 24 weeks (9/9
132   tested animals; Fig. 1B, C). However, 3MC-treated NMRs did not develop tumors in a period of 114
133   weeks (0/9 tested animals; Fig. 1B, C, and Fig. S1A). Histopathological analysis (three animals)
134   showed no obvious abnormalities (Fig. 1C). The remaining animals were kept alive, and no visible

135 tumors were observed for 177 weeks. NMRs who received a subcutaneous injection of 3MC also
136 did not develop visible tumors for 97 weeks (0/5 tested animals; Fig. 1D–F). No obvious
137 histopathological abnormalities such as hyperplasia were detected although Ki67-positive cells
138 tended to increase slightly (Fig. 1F and Fig. S1B). On the other hand, the mice developed severe
139 skin ulcers and had to be euthanized within 10 weeks (Fig. S1C).
140　　　　Next, other carcinogens, namely, 7,12-dimethylbenz[a]anthracene (DMBA) and 12-*O*-
141 tetradecanoylphorbol-13-acetate (TPA) (23), were administered to the back skin of mice and NMRs
142 (Fig. 1G). All mice developed multiple papillomas within 30 weeks (6/6 tested animals; Fig. 1H, I).
143 On the other hand, NMRs did not develop any visible tumors at 55 weeks, and histopathological
144 analysis of skin biopsies showed no obvious abnormalities, although Ki67-positive cells increased
145 slightly (0/6 tested animals; Fig. 1H, I, and Fig. S1D). These animals continued to receive TPA and
146 did not develop tumors for 116 weeks.
147
148 **Carcinogens increase tissue damage in NMRs**
149
150 To evaluate the early tissue responses to the carcinogen, 3MC was injected subcutaneously, and
151 the effects were analyzed after 1 week (24) (Fig. 2A). NMR and mouse skin tissues showed
152 increased phospho-histone H2A.X (pH2AX)-positive or 8-hydroxy-2′-deoxyguanosine (8-OHdG)-
153 positive DNA-damaged cells in response to 3MC treatment, and TUNEL-positive dead cells were
154 similarly increased (Fig. 2B, C and Fig. S2).
155　　　　We then evaluated the tissue responses to DMBA at earlier stages (Fig. 2D). Similar to the
156 effect of 3MC, DMBA treatment for 24 h significantly increased the number of pH2AX-positive DNA-
157 damaged cells in both mouse and NMR skin (Fig. 2E, F). Taken together, these results demonstrate
158 that treatment with carcinogenic agents increased tissue damage such as DNA damage and cell
159 death in NMR tissues. Despite this increasing tissue damage, NMR individuals showed marked
160 resistance against two types of chemical carcinogenesis induction.
161
162 **NMRs show dampened tissue inflammatory responses after carcinogenic insults**
163
164 The effect of chemical carcinogens on immune cell infiltration was evaluated by immunostaining
165 using pre-validated antibodies against CD45 (leukocytes), IBA1 (macrophages), myeloperoxidase
166 (MPO, myeloid cells: neutrophils and macrophages), and CD3 (T cells) (Fig. S3A and Dataset S1).
167 In mice, 3MC treatment significantly increased the number of CD45-, IBA1-, and CD3-positive
168 immune cells at 1 and 3 weeks (Fig. 3A–C, Fig. S4, and Fig. S5A, B). These data reflect the
169 infiltration of inflammatory immune cells after carcinogen treatment in mouse tissues as previously
170 reported (16, 17). By contrast, 3MC-treated NMR skin showed very low levels of several types of
171 immune cell infiltration at 1 and 3 weeks. Analysis of NMR skin at 97 weeks after 3MC treatment
172 showed no significant increase in CD45-positive immune cells (Fig. 3A–C, Fig. S4, and Fig. S5).
173 Similar to the results regarding the effects of 3MC, DMBA/TPA-treated NMR skin at 2 weeks
174 showed a very small increase in the number of several immune cell types in contrast with mice
175 (Fig. 3D–F and Fig. S6A, B). The accumulation of immune cells was markedly attenuated in NMR
176 skin after 55 weeks of DMBA/TPA treatment, including after 108 rounds of treatment with TPA, a
177 potent inflammatory agent (Fig. 3F and Fig. S6C). These results indicate that infiltration of
178 inflammatory immune cells was much lower in NMRs than in mice after exposure to two types of
179 chemical carcinogens.
180　　　　Furthermore, we evaluated skin tissue responses to UV irradiation, which promotes
181 carcinogenesis by inducing DNA damage and inflammation in mice (16, 25) (Fig. S7A). UVB
182 irradiation significantly increased skin thickness, the number of pH2AX-positive DNA-damaged
183 cells, TUNEL-positive dead cells, and cleaved caspase-3-positive apoptotic cells in both mouse
184 and NMR skin, indicating that tissue damage increases in both species (Fig. S7B, C). In mouse
185 skin, UV irradiation resulted in significant increases in the numbers of CD45-, IBA1-, and MPO-
186 positive inflammatory immune cells, whereas in NMR skin, UV irradiation resulted in very small
187 increases in the numbers of CD45- and CD3-positive immune cells, and no significant increase in
188 IBA1- or MPO-positive immune cells (Fig. S8). These results indicate that the accumulation of

4

189   inflammatory immune cells in response to various cancer-promoting stimuli is attenuated in NMRs,
190   despite the induction of tissue damage such as DNA damage and cell death.
191   Next, we evaluated infection-associated inflammatory responses in NMRs (Fig. S9A).
192   Subcutaneous injection of bacterial lipopolysaccharide (LPS), which reportedly activates NMR
193   immune cells (26), increased interleukin-6 (*IL6*) expression, as well as the number of CD45- and
194   MPO-positive immune cells in both mouse and NMR skin (Fig. S9B–D). Intraperitoneal LPS
195   injection significantly increased the number of IBA1-positive cells in NMR livers (Fig. S10A). Thus,
196   NMR immune cells can infiltrate into tissues in response to bacterial virulence factors. When co-
197   cultured with dead NMR fibroblasts, NMR macrophages exhibited normal phagocytic activity of
198   dead cells (Fig. S10B) despite showing reduced infiltration into carcinogen-treated damaged
199   tissues.
200   During these experiments, we observed that the number of immune cells was lower in
201   control NMR skin than in control mouse skin. To provide a context for this, we examined the number
202   of tissue-resident immune cells in liver, skin, and intestine from mice, rats, guinea pigs, and NMRs.
203   We found that the number of IBA1- or CD3-positive immune cells was lower in some NMR tissues,
204   suggesting unique tissue immune homeostasis in NMRs (Fig. S11, S3).
205   To investigate the overall inflammatory responses to 3MC, UV, and LPS treatment, we
206   performed global gene expression analysis using RNA-sequencing (RNA-seq). Changes in global
207   gene expression or in selected ligand genes important for cell-to-cell communication, including
208   many chemokines and cytokines (27), in response to the different treatments were greater in mouse
209   skin than in NMR skin, and the upregulations were particularly large in the 3MC- and UV-treated
210   mouse groups (Fig. S12A, B and Dataset S2). Cell type enrichment analysis using xCell (28)
211   showed that all treatments significantly increased several immune cell enrichment scores in mouse
212   skin (Fig. S12C and Dataset S3). By contrast, in NMR skin, 3MC and UV treatment did not
213   significantly change the immune cell enrichment scores, whereas LPS did (Fig. S12C and Dataset
214   S3). These results are consistent with those of immunohistochemical analyses of immune cell
215   markers (Fig. 3 and Figs. S4, S5, S6, S8, S9), and confirm that inflammatory responses to cancer-
216   promoting stimuli are attenuated in NMR tissues.
217
218   **Loss-of-function mutations in necroptosis regulators in NMRs may contribute to the**
219   **attenuated tissue inflammatory response and carcinogenesis resistance**
220
221   To examine the mechanisms underlying the different responses of NMR tissues to cancer-
222   promoting stimuli, we analyzed differentially expressed genes (DEGs) in response to 3MC and UV
223   treatment that differed from DEGs in response to LPS treatment between mice and NMRs. We
224   selected genes that were species-specifically upregulated by >2 fold in NMRs or mice after both
225   3MC and UV treatment, but that were not commonly upregulated after LPS treatment (Fig 4A, blue-
226   filled area, collectively termed 3MC-UV Mouse-DEGs and Fig. S13A, purple-filled area, collectively
227   termed 3MC-UV NMR-DEGs). Enrichment analysis of the selected DEGs was performed using
228   Metascape (29). Among 3MC-UV NMR-DEGs, genes related to the Kyoto Encyclopedia of Genes
229   and Genomes (KEGG) pathway "p53 signaling pathway" were highly enriched, suggesting
230   activation of the p53 pathway in 3MC- and UV-treated NMR skin (Fig. S13A and Dataset S4). This
231   was consistent with the immunostaining data showing increased DNA damage and cell death in
232   3MC- and UV-treated NMR skin (Fig. 2B, C, and Fig. S2, S7). Among 3MC-UV Mouse-DEGs,
233   genes related to the KEGG pathway "Cytokine-cytokine receptor interaction" and the gene ontology
234   (GO) term "Leukocyte migration" were highly enriched, indicating the activation of inflammatory
235   responses in 3MC- and UV-treated mouse skin (Fig. 4A and Dataset S4).
236   Notably, among 3MC-UV Mouse-DEGs, genes related to the KEGG pathways "RIPK1-
237   mediated regulated necrosis" (necroptosis) and "Regulation of cell killing" were the most
238   significantly enriched (Fig. 4A and Dataset S4), which were not observed among 3MC-UV NMR-
239   DEGs. Necroptosis, a type of programmed necrotic cell death, triggers inflammation, and promotes
240   colon and pancreatic cancer development (14, 30–32). Thus, we hypothesized that inactivation of

5

241 necroptosis in NMRs may underlie the attenuated inflammatory responses in NMRs, possibly
242 leading to cancer resistance.
243   The RIPK1-RIPK3 complex induces necroptosis via the necroptosis effector, MLKL (33–
244 35). We found that the NMR genome harbors a two-nucleotide insertion in the *RIPK3* gene and a
245 two-nucleotide deletion in the *MLKL* gene, both of which cause frame-shift mutations and introduce
246 premature stop codons (Fig. 4B). These alterations remove the RHIM domain in RIPK3 and the
247 pseudokinase domain in MLKL, which are both functionally essential for necroptosis in other
248 mammalian species (36). Because NMR *RIPK3* and *MLKL* genes have premature stop codons
249 located before the final exon, the transcripts from these two genes are putative targets for
250 nonsense-mediated mRNA decay (NMD) (37). As NMR *RIPK3* mRNA was expressed in the skin
251 (Fig. S13B, C), we examined whether NMR *RIPK3* is degraded by NMD. RT-qPCR analysis of
252 NMR fibroblasts treated with actinomycin D (ActD, a transcriptional inhibitor) and/or cycloheximide
253 (CHX, a translational inhibitor that potently inhibits NMD) showed that NMR *RIPK3* transcripts
254 exhibited relatively low steady-state levels after ActD treatment, whereas the *RIPK3* mRNA level
255 increased upon CHX treatment (Fig. S13D). This result indicates that NMR *RIPK3* mRNA is
256 degraded by NMD. NMR *MLKL* mRNA expression was not detected in the skin (Fig. S13E–G).
257 Although previous studies have shown that only the N-terminal 4-alpha helical bundle domain of
258 MLKL can cause spontaneous cell death depending on the cellular context (38–40), NMR MLKL
259 could not induce spontaneous cell death (Fig. S14A, B). Thus, the genes essential for necroptosis
260 induction are likely to be defective in NMRs.
261   To evaluate whether necroptosis is impaired in NMRs, we performed experimental
262 necroptosis induction in vitro. In mouse fibroblasts, treatment with tumor necrosis factor-α (TNF-
263 α), CHX, and z-VAD-fmk (caspase inhibitor) caused massive cell death, which was inhibited by
264 necrostatin-1 (Nec1, RIPK1 inhibitor), as previously reported (41), indicating activation of
265 necroptosis (Fig, 4C). In contrast to mouse fibroblasts, NMR fibroblasts did not show increased cell
266 death in response to TNF-α + CHX or TNF-α + CHX + z-VAD-fmk, although TNF-α upregulated
267 *IL6* (42) as observed in mice (Fig. 4C and Fig. S14C). These results suggest that NMR cells are
268 incapable of inducing TNF-α-mediated necroptosis and apoptosis, although they are capable of
269 inducing DNA damage-induced caspase-3-dependent apoptosis (Fig. S14D–F). In mice, RIPK3 is
270 important for the induction of both necroptosis and TNF-induced apoptosis mediated by RIPK1
271 (43). Thus, the loss-of-function mutation of *RIPK3* in NMRs may contribute to their inability to
272 undergo necroptosis and TNF-induced apoptosis mediated by RIPK1.
273   Generally, necroptosis triggers inflammation through the release of various cellular
274 components such as high mobility group box-1 protein (HMGB1) (44), which can be observed
275 during cancer progression (16, 17). 3MC, DMBA, and UV treatment did not significantly alter
276 cytoplasmic HMGB1 translocation in NMR skin, in contrast to the significant increase observed in
277 mouse skin (Fig. 4D, E and Fig. S15). These results further support the idea that the inability to
278 induce necroptosis in NMRs may contribute to the dampened immune cell responses to
279 carcinogenic stimuli.
280   Next, we assessed whether the necroptosis inhibitor (45) GSK'872, a RIPK3 inhibitor, or
281 disruption of the *Ripk3* gene could suppress the 3MC-induced inflammatory response in mice and
282 impede carcinogenesis as observed in NMRs (Fig. 4F and Fig. S16, S17A). The results of western
283 blotting showed that 3MC treatment activated the MLKL protein (as indicated by MLKL
284 phosphorylation), and MLKL activation was suppressed by GSK'872 treatment (Fig. S17B).
285 GSK'872 and disruption of the *Ripk3* gene significantly suppressed cytoplasmic HMGB1
286 translocation (Fig. S17C), indicating that necroptosis was successfully suppressed. In addition,
287 both manipulations reduced the infiltration of inflammatory immune cells in 3MC-treated mouse
288 skin (Fig. S17D). Finally, we evaluated the effect of GSK'872 treatment or *Ripk3* knockout on 3MC-
289 induced chemical carcinogenesis in mice (Fig. 4F). Continuous administration of GSK'872 or
290 disruption of the *Ripk3* gene significantly delayed the onset of carcinogenesis in 3MC-treated mice
291 (Fig. 4G; *P* = 0.0423 for GSK'872; *P* = 0.0228 for *Ripk3* KO mice; Gehan–Breslow–Wilcoxon test).
292 Thus, in mice, the suppression of the necroptosis regulator attenuated immune cell infiltration and
293 chemical carcinogenesis. This result is consistent with our assumption that the absence of

6

294 necroptosis regulators in NMRs may contribute to the reduced inflammatory response and
295 resistance to chemical carcinogenesis.
296
297 **Discussion**
298
299 In this study, NMRs showed marked resistance to two types of chemical carcinogenesis induction
300 in vivo. The distinctive feature of the NMR tissue response to carcinogenic insults was an unusual
301 dampened inflammatory response, which may serve as a non-cell-autonomous cancer resistance
302 mechanism in NMR individuals. Inhibition of RIPK3 in mice resulted in the reduced inflammatory
303 response and the delayed onset of carcinogenesis (Fig. S18). Therefore, we propose that one of
304 the mechanisms underlying the attenuated tissue inflammatory response and remarkable cancer
305 resistance of NMRs may be specific loss-of-function mutations in the necroptosis regulators
306 *RIPK3* and *MLKL*.
307   In a different cancer-resistant rodent, the blind mole-rat, the same dose of 3MC causes
308 low frequency carcinogenesis (~9%) (22, 46). Thus, NMRs are especially resistant to chemical
309 carcinogenesis. In contrast to NMRs, 3MC induces massive inflammation in blind mole-rats (22).
310 This distinct difference in inflammatory responses between NMRs and blind mole-rats, both of
311 which show spontaneous cancer resistance and a high DNA repair capacity (47–49), may
312 contribute to the differences in resistance to in vivo carcinogenesis induction.
313   The attenuated cancer-promoting tissue inflammatory response may act as a gatekeeper
314 to prevent carcinogenesis in NMRs. This is supported by previous reports showing that toll-like
315 receptor 4 knockout mice exhibit carcinogenic resistance owing to dampened inflammatory
316 responses (16, 17). Other mechanisms besides the deficiency in necroptosis, especially those
317 related to immune cell characteristics, might also contribute to the unique inflammatory response
318 in NMRs. Immune homeostasis in NMRs may be unusual because the resident immune cells,
319 which contribute to the attenuated immune response and to cancer resistance in mice (50, 51),
320 were less numerous in some tissues of NMRs than in those of other rodent species (Fig. S11).
321 Moreover, a single cell RNA-seq study of immune cells revealed the unique immune system of
322 NMRs, which is characterized by a lack of natural killer cells (26). Recent in silico and in vitro
323 studies have shown that cancer-resistant bats lack certain immunity-related genes (52, 53).
324 Future studies examining the immune system of cancer-resistant animals should improve our
325 understanding of their cancer resistance mechanisms.
326   The type of cell death and its modulation play critical roles in the regulation of
327 inflammation and homeostasis in vivo. In this study, caspase-3-dependent apoptosis occurred in
328 NMRs, whereas necroptosis did not (Fig. 4C–E, Fig. S7B, C, Fig. S14D–F, and Fig. S15). Since
329 the pro-inflammatory potential of necroptosis is markedly higher than that of apoptosis (44), the
330 suppression of necroptosis may contribute substantially to the attenuation of the inflammatory
331 response in NMR tissues as in RIPK3 inhibited/disrupted mice. Necroptosis is involved in a
332 variety of inflammatory age-related diseases/disorders, such as ischemia-reperfusion injury,
333 atherosclerosis, and neurodegenerative diseases. On the other hand, necroptosis also plays an
334 important role in innate immunity during infectious diseases (19). Notably, NMRs are resistant not
335 only to cancer, but also to aging-related declines in biological function, neurodegenerative
336 disease, and ischemia-reperfusion injury, although they exhibit high susceptibility to herpes virus
337 infection (3, 54–56). It is possible that deficiency in necroptosis induction may constitute an
338 important part of the mechanisms responsible for the unusual characteristics of NMRs. It would
339 also be interesting to study how other types of cell death, such as ferroptosis and pyroptosis, are
340 regulated in NMRs.
341   Recent studies have shown that RIPK3 is involved not only in the induction of necroptosis
342 and RIPK1-mediated apoptosis, but also in the activation of the NLRP3 inflammasome,
343 maturation of IL-1β, and production of inflammatory cytokines, all of which are not directly
344 activated via necroptosis (57). MLKL contributes to various biological functions, such as
345 endosomal trafficking and extracellular vesicle formation, in addition to the induction of
346 necroptosis and inflammatory cytokines (58). Therefore, the loss-of-function mutations of *RIPK3*
347 and *MLKL* in NMRs may affect not only necroptosis, but also the attenuation of the tissue

7

348   inflammatory response via suppression of the NLRP3 inflammasome and various other biological
349   processes in vivo. This will require further analysis.
350   In addition to the role of cancer-promoting inflammation, the generation of mutant cells is
351   also crucial for the initiation of carcinogenesis (59). Although carcinogen treatment damaged DNA
352   and cells in NMR skin (Fig. 2 and Fig. S2, S7), it is possible that NMRs are protected against
353   mutant cell generation or efficiently eliminate mutant cells. Possible explanations include 1)
354   inhibition of mutant cell generation via several mechanisms, such as the previously reported
355   efficient DNA double-strand break repair (48), or 2) elimination of mutant cells by unknown
356   mechanisms, which may synergistically contribute to the in vivo cancer resistance of NMRs.
357   The present results demonstrate the importance of research into the unusual tissue
358   immune response and extraordinary resistance to carcinogenesis of NMR individuals. Further
359   insight into the tissue responses of the NMR to carcinogenic insults may lead to the development
360   of new anticancer strategies for humans.
361
362
363   **Materials and Methods**
364
365   **Animals**
366   NMRs were maintained at Kumamoto University and Hokkaido University. All NMRs (8–31
367   months) used in this research were raised in rooms that were maintained at 30°C ± 0.5°C and
368   55% ± 5% humidity with 12 h light and 12 h dark cycles (10). The NMRs used in this study are
369   listed in Dataset S5. Male C57BL/6N mice (8–10 weeks) were purchased from CLEA Japan, and
370   *Ripk3* knockout (KO) mice were generated by deletion of the *Ripk3* gene. Wild-type mice and KO
371   mice were kept in rooms that were maintained at 24.5°C ± 1.5°C and 50% ± 10% humidity with
372   12 h light and 12 h dark cycles. Male rats (Wistar, 6 months) and guinea pigs (Hartley, 6 months)
373   were purchased from Japan SLC. The Ethics Committees of Kumamoto University (approval no.
374   A30-043 and A2020-042) and Hokkaido University (14-0065) approved all procedures, which
375   were in accordance with the Guide for the Care and Use of Laboratory Animals (United States
376   National Institutes of Health, Bethesda, MD, USA).
377
378   **Generation of *Ripk3* knockout mice and genotyping**
379   *Ripk3* KO mice were generated by introduction of the Cas9 protein (317–08441; NIPPON GENE),
380   tracrRNA (GE-002; FASMAC), synthetic crRNA (FASMAC), and ssODN into C57BL/6N fertilized
381   eggs by electroporation. For generating the *Ripk3* KO allele, the synthetic crRNAs were designed
382   according to the sequence AAGAGAGACTGGCTATCGTG (GGG) of the 5′ upstream region of
383   *Ripk3* and ACTAGGAGAGGATCCCACTG (AGG) in the *Ripk3* intron 9. The ssODN 5′-
384   CGACTTTCTTTCGTTGTGTGACCTCAGttttatttGATAGCCAGTCTCTCTTGGACCCCTTAGCTCC
385   ACC-3′ was used as a homologous recombination template.
386   The electroporation solution contained 10 μM tracrRNA, 10 μM synthetic crRNA, 0.1
387   mg/mL Cas9 protein, and 1 μg/μL ssODN in Opti-MEM I Reduced Serum Medium (31985062;
388   Thermo Fisher Scientific). Electroporation was performed using the Super Electroporator NEPA
389   21 (NEPA GENE) on glass microslides with round wire electrodes (1.0 mm gap [45–0104; BTX]).
390   Four steps of square pulses were applied (1], three times of 3 mS poring pulses with 97 mS
391   intervals at 30 V; 2], three times of 3 mS polarity-changed poring pulses with 97 mS intervals at
392   30 V; 3], five times of 50 mS transfer pulses with 50 mS intervals at 4 V with 40% decay of
393   voltage per pulse; 4], five times of 50 mS polarity-changed transfer pulses with 50 mS intervals at
394   4 V with 40% decay of voltage per pulse).
395   The targeted *Ripk3* KO allele in F0 mice was identified by genomic PCR using the
396   following primers: Ripk3 KO F: 5′- AGCGACACCTTGTGATCTCC-3′ and Ripk3 KO R: 5′-
397   CTGGCCCAAGACAACCCTTA -3′ for the knockout allele (396 bp); Ripk3 Wild F: 5′-
398   GGAAAAGTCAGCCAATCCCG -3′ and Ripk3 Wild R: 5′- GCAAGACTAGAGCACACCCTC -3′ for
399   the wild-type allele (375 bp).
400
401   **3MC treatment**

402   C57BL/6N mice (average body weight, 24.0 g), NMRs (average body weight, 26.6 g), and *Ripk3*
403   KO mice were intramuscularly or subcutaneously injected with 3MC (Sigma-Aldrich; 1 mg
404   dissolved in 100 μL corn oil) into the hindlimbs or back skin (60). Animals were observed weekly
405   until tumors >15 mm in diameter developed at the injected sites, at which point the animals were
406   sacrificed humanely using isoflurane anesthesia, and the tumors were used for further analysis.
407   For NMRs, muscle samples (3MC-injected sites and opposite sites as controls) collected after
408   114 weeks and skin samples collected after 97 weeks were used for histopathological analysis.
409   To evaluate responses to short exposure to 3MC, 3MC (1 mg dissolved in 100 μL corn
410   oil) was subcutaneously injected into the back skin of C57BL/6N mice or NMRs, and the site was
411   examined at 1 or 3 weeks after injection. Injected sites (100 mm^2) were collected and used for
412   further analysis. To suppress RIPK3 activity, GSK'872 (31, 45) (SelleckBio; 1 mg/kg body weight
413   dissolved in saline) was intraperitoneally injected three times a week from 1 week before 3MC
414   treatment until the end point of the experiment.
415
416   **DMBA/TPA treatment**
417   C57BL/6N mice and NMRs were treated with DMBA (Sigma-Aldrich; 100 μg in 100 μL acetone)
418   on the back skin. One week after DMBA treatment, animals were treated twice a week with TPA
419   (Cayman Chemical; 12.5 μg in 100 μL acetone) until tumor formation was observed (61). Animals
420   were observed daily until tumors >7 mm in diameter developed on the skin, at which point the
421   animals were sacrificed humanely by isoflurane anesthesia, and the tumors were used for further
422   analysis. For NMRs, skin biopsies were performed under isoflurane anesthesia at 55 weeks, and
423   samples were used for histopathological analysis. For histopathological analysis, one individual
424   who had an external wound possibly due to fighting was excluded as previously described (23).
425   To evaluate responses to short exposure to DMBA, DMBA (100 μg in 100 μL acetone)
426   was administered to the back skin, and skin biopsies were performed after 24 h. To evaluate
427   responses to short exposure to DMBA/TPA, DMBA (100 μg in 100 μL acetone) was administered
428   to the back skin, and 1 week after DMBA treatment, animals were subsequently treated three
429   times with TPA (12.5 μg in 100 μL acetone). Skin biopsies were performed 1 week after starting
430   TPA treatment.
431
432   **Hematoxylin and eosin (HE) staining and immunohistochemical analysis**
433   Histological examination was performed at K.I. Stainer, Inc. (Kumamoto, Japan). Briefly, the
434   samples were fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS), embedded in
435   paraffin, and cut into 4 μm sections; HE staining was routinely performed. The antibodies and
436   protocols are listed in Dataset S1. Briefly, for immunostaining, the sections were deparaffinized
437   using xylene and rehydrated with a graded series of ethanol. Antigen retrieval was performed by
438   heat-induced epitope retrieval in citrate buffer or Tris buffer, or by enzymatic retrieval using
439   proteinase K (62). The sections were incubated with 1% bovine serum albumin in Tris-buffered
440   saline with 0.1% NaN$_3$ for blocking, and stained with primary antibodies against CD45 (Abcam,
441   ab10558), MPO (DAKO, A0398), IBA1 (FUJIFILM WAKO, 019-19741), CD3 (Nichirei, 413591),
442   Ki67 (Abcam, ab16667), 8-OHdG (Santa Cruz Biotechnology, sc-393871), pH2AX (Cell Signaling
443   Technology [CST], 9718), or HMGB1 (Abcam, ab79823). The sections were incubated with
444   horseradish peroxidase (HRP)-conjugated anti-rabbit, anti-mouse, or anti-rat secondary
445   antibodies (Nichirei) as a secondary antibody. Positive signals were visualized using HistoGreen
446   substrate (Cosmo Bio) for staining of immune cells in the skin (because it is not easy to
447   distinguish diaminobenzidine (DAB)-stained cells from dermal melanin pigments in NMR skin in
448   limited-sized figures) or DAB (Nichirei). For HMGB1, Alexa Fluor 555 anti-rabbit IgG (CST,
449   A21429) secondary antibody was used. Nuclei were counterstained with hematoxylin (for CD45,
450   MPO, IBA1, CD3, Ki67, 8-OHdG, and pH2AX) or Hoechst 33258 (Sigma-Aldrich) for HMGB1.
451   For cleaved caspase-3, 10 μm fresh-frozen sections were fixed with 4% PFA, washed with PBS,
452   and blocked with 5% normal goat serum in 0.3% Triton X-100 (Nacalai Tesque) in PBS. The
453   sections were incubated with primary antibodies against cleaved caspase-3 (CST; 9664; 1:400) in
454   Can Get Signal Solution B (TOYOBO). The sections were stained with Alexa Fluor 555 anti-rabbit

9

455   IgG (CST; A21429; 1:1000) as a secondary antibody, and nuclei were stained with 1 μg/mL
456   Hoechst 33258 (Sigma-Aldrich).
457   The images were captured using a BZ-X 710 fluorescence microscope (KEYENCE) and
458   analyzed using a BZ-X image analyzer (KEYENCE).
459
460   **TUNEL staining**
461   For TUNEL staining, 4 μm paraffin sections were deparaffinized and rehydrated as described
462   above. The sections were stained using the TUNEL Assay Kit BrdU-Red (Abcam) according to
463   the manufacturer's instructions. Nuclei were counterstained with Hoechst 33258. The images
464   were captured using a BZ-X 710 fluorescence microscope and analyzed using a BZ-X image
465   analyzer (KEYENCE).
466
467   **Morphometric analyses of skin inflammatory responses**
468   Epidermal thickness was quantified by calculating the mean length of skin surface to the
469   epidermal junction by five hand-drawn line segments per field (four fields were analyzed per
470   animal) using ImageJ. Positive cells identified by immunostaining and TUNEL staining were
471   quantified by counting the mean number of cells in each of the four images of one section from
472   more than three animals per experiment, and were normalized to the total number of cells (for
473   Ki67, TUNEL, pH2AX, 8OHdG, cleaved caspase-3, CD45, IBA1, MPO, and CD3) or to the tissue
474   area (for CD45, IBA1, MPO, and CD3). The quantification was performed by three independent
475   investigators including a pathologist (Y. Komohara). Total cells, either Hoechst or hematoxylin-
476   positive nuclei (at least 350 cells per animal) and tissue area (bright field), were measured using
477   a Hybrid Cell Count application (KEYENCE) in a BZ-X image analyzer.
478   Cytoplasmic HMGB1-positive cells were quantified by counting the mean number of cells
479   in highly magnified sections from more than three animals per experiment, and normalized to the
480   number of total HMGB1-positive cells (at least four images from one section per animal, >100
481   cells). The quantification was performed by two independent investigators.
482
483   **UV irradiation**
484   UV irradiation on the back skin of C57BL/6N mice and NMRs was performed every other day for
485   12 days with a dose of 1,000 J/m^2 using a UV lamp (UVP UVM-28; Analytic Jena) for the times
486   indicated in Fig. S7A (25). Prior to irradiation, the back skin of C57BL/6N mice was shaved. At 24
487   h after final irradiation, the animals were sacrificed humanely using isoflurane anesthesia, and the
488   skin samples were used for further analysis.
489
490   **LPS treatment**
491   C57BL/6N mice and NMRs were subcutaneously or intraperitoneally injected with LPS (Sigma-
492   Aldrich; 10 mg/kg body weight dissolved in saline). After 24 h of treatment, the animals were
493   sacrificed humanely using isoflurane anesthesia, and skin or liver samples were used for further
494   analysis.
495
496   **RNA isolation and quantification of gene expression**
497   Total RNA was extracted using the RNeasy Plus Mini Kit (Qiagen, for cells) or TRIzol (Thermo
498   Fisher Scientific, for tissues) according to the manufacturer's protocol. The gDNA Eliminator Spin
499   Column (Qiagen) or TURBO DNA-free™ Kit (Invitrogen) was used for genomic DNA elimination
500   according to the manufacturer's protocol. Reverse transcription reactions were performed with
501   ReverTra Ace qPCR RT Master Mix (TOYOBO) using 300 ng total RNA as a template. The
502   resulting cDNA was used for reverse transcription polymerase chain reaction (RT-PCR) and
503   quantitative reverse transcription PCR (RT-qPCR). For RT-PCR, 24 cycles (for *actin beta* [*ACTB*])
504   or 35 cycles (for *MLKL*) of amplification were performed under the following conditions using
505   PrimeSTAR Max DNA Polymerase (Takara): denaturing at 98°C for 10 s, annealing at 55°C for
506   30 s, and extension at 72°C for 30 s. The DNA fragments were electrophoresed in 2% agarose
507   gels. RT-qPCR analysis was performed using Thunderbird SYBR qPCR Mix (TOYOBO) or

508   PowerUp SYBR Green Master Mix (Thermo Fisher Scientific) on a CFX384 Touch Real-Time
509   PCR Detection System (Bio-Rad) with the primers listed in Dataset S6 (63).
510
511   **Cell culture**
512   Primary NMR or mouse skin fibroblasts were obtained from the back skin of 1–2-year-old NMRs
513   or 6–8-week-old C57BL/6N mice (10). The cells were cultured in Dulbecco's modified Eagle's
514   medium (Sigma-Aldrich) supplemented with 15% fetal bovine serum (FBS) (for NMR fibroblasts)
515   or 10% FBS (for mouse fibroblasts) (Gibco), 1% penicillin/streptomycin (FUJIFILM WAKO), 2 mM
516   L-glutamine (FUJIFILM WAKO), and 0.1 mM non-essential amino acids (FUJIFILM WAKO) at
517   32°C in a humidified atmosphere containing 5% O_2 and 5% CO_2. We used the fibroblasts within
518   five passages. The medium was replaced every 2 days. For investigation of NMD, NMR
519   fibroblasts were incubated with 5 μg/mL ActD (Sigma-Aldrich) and/or 30 μg/mL CHX (FUJIFILM
520   WAKO) for 4 h. NMR fibroblasts treated with DMSO served as the control. After treatment, total
521   RNA was isolated and used for RT-qPCR as described above.
522
523   **Lentiviral overexpression of NMR-MLKL**
524   Because NMR MLKL mRNA was not expressed in NMR skin, the coding sequence of NMR-
525   MLKL was artificially synthesized based on the NCBI sequence information and our genomic
526   sequencing results (XM_021256495.1 and Fig. 4B) (Eurofins Genomics) and inserted into the
527   lentiviral vector pCSII-EF-RFA-hyg (kindly provided by H. Naka-Kaneda). Then, the pCSII-EF-
528   NMR-MLKL plasmid and packaging vectors (pCMV-VSV-G-RSV-Rev and pCAG-HIVgp) (64)
529   were used to transfect 293T cells using a polyethylenimine MAX transfection reagent (CosmoBio)
530   according to the manufacturer's instructions. The conditioned medium containing viral particles
531   was concentrated by ultracentrifugation and used for viral transduction into NMR SV40ER cells,
532   an NMR skin fibroblast cell line expressing simian virus 40 early region (65). The infected cells
533   were passaged and subjected to propidium iodide (PI) staining as follows.
534
535   **Necroptosis assay**
536   Primary mouse or NMR fibroblasts were seeded at 1 × 10^4 cells/well onto 24-well plates and
537   stimulated with TNF-α (PeproTech; 50 ng/mL), z-VAD-fmk (Abcam; 20 μM), CHX (1 μg/mL), and
538   Nec-1 (Sigma-Aldrich; 20 μM). After 24 h, cells were stained with Hoechst 33342 (DOJINDO; 1
539   μg/mL) for 10 min at 32°C. Then, the cells were stained with PI (FUJIFILM Wako; 10 μg/mL) for 5
540   min at 32°C. Images were captured using a BZ-X 710 fluorescence microscope (KEYENCE), and
541   the number of cells positive for PI or Hoechst 33342 was counted (at least 100 cells per
542   treatment) using a BZ-X image analyzer (KEYENCE). PI and Hoechst 33342 double-positive cells
543   were regarded as dead cells.
544
545   **Etoposide treatment**
546   NMR fibroblasts were exposed to etoposide at 200 μM for 4 days. Etoposide-containing medium
547   was added to subconfluent fibroblasts. After 2 days, the medium was replaced by freshly
548   prepared etoposide-containing medium for an additional 2 days. Then, the cells were collected for
549   Annexin V/PI analysis and western blotting.
550
551   **Flow cytometry analysis for apoptosis detection**
552   The FITC Annexin V Apoptosis Detection Kit (BD Biosciences or BioLegend) was used for the
553   detection of apoptosis. Primary NMR skin fibroblasts were stained according to the
554   manufacturer's protocols and analyzed on a FACSVerse (BD Biosciences) flow cytometer.
555
556   **Phagocytosis assay**
557   NMRs and mice were sacrificed humanely using isoflurane anesthesia, and limbs were isolated.
558   After removing muscles and cartilage tissue, the bones were crushed and suspended in PBS.
559   The cell suspension was filtered through a 70 μm cell strainer (Falcon) and suspended in hypo-
560   osmotic solution to remove red blood cells. The remaining cells after hemolysis were processed
561   into a single cell suspension and cultured in RPMI-1640 (FUJIFILM WAKO) supplemented with

11

562   15% FBS, 1% penicillin/streptomycin, 2 mM L-glutamine, 0.1 mM non-essential amino acids, and
563   20 ng/mL mouse macrophage colony stimulating factor (M-CSF) (BioLegend) for 8 days (66).
564   Dead cells were prepared by 200 J/m^2 of UVC irradiation to fibroblasts using a UV crosslinker
565   (Analytic Jena). After UV irradiation, cells were cultured for 24 h, and dead cells were collected
566   and stained using pHrodo (Thermo Fisher Scientific) according to the manufacturer's protocol.
567   The same amounts of pHrodo-labeled dead cells (5×10^5 cells) were co-incubated with NMR or
568   mouse bone marrow macrophage culture. After 2 h, phagocytosis was evaluated by measuring
569   pH-sensitive fluorescence of pHrodo using the BZ-X image analyzer (KEYENCE).

570

571   **RNA-seq analysis**
572   Total RNA was extracted from mouse and NMR skin tissues using TRIzol (Thermo Fisher
573   Scientific) and purified using the RNeasy Plus Mini Kit (Qiagen). Any contamination with genomic
574   DNA was removed from total RNA using the RNase-Free DNase Set (Qiagen) according to the
575   manufacturer's protocol. cDNA libraries were generated from 200 ng total RNA using a TruSeq
576   stranded mRNA library preparation kit (Illumina). The resultant libraries were sequenced on
577   NextSeq550 (Illumina) in single-ended mode. Low-quality bases and the adapters in the
578   sequenced reads were trimmed using Cutadapt (ver.1.14) (67) with Python 2.7.6. The trimmed
579   reads were mapped to either the mouse (mm10) or NMR (HetGla_female_1.0) reference
580   genome, with the UCSC refGene gtf for mouse and the Ensembl HetGla gtf and previously
581   published gff (68) for NMR, using STAR (ver.2.4.1d) (69). For identification of DEGs, the uniquely
582   mapped reads were counted and normalized to calculate fold changes and false discovery rate
583   (FDR) using HTSeq (ver.0.11.2) (70) and edgeR (ver.3.18.1) (71), with the UCSC refGene gtf for
584   mouse and the Ensembl HetGla gtf and previously published gff (68) for NMR. Enrichment of
585   genes in specific cellular functions (GO terms, Reactome, and KEGG pathways) was analyzed
586   using Metascape (29). The gene expression levels were calculated as transcripts per million
587   (TPM) using deepTools (ver.2.1.0) (72), and mapping was visualized using the Integrative
588   Genomics Viewer. The immune enrichment score was analyzed using xCell (28).

589

590   **Western blotting**
591   The skin or cell samples were lysed in cell-lysis buffer (125 mM Tris-HCl, pH 6.8, 4% sodium
592   dodecyl sulphate [SDS], and 10% sucrose) and boiled for 10 min. Protein concentration was
593   measured using the BCA Protein Assay Kit (Takara Bio). The protein samples were subjected to
594   SDS-polyacrylamide gel electrophoresis and transferred to polyvinylidene fluoride membranes
595   using the Trans-Blot Turbo Transfer System (Bio-Rad). Membranes were probed with antibodies
596   against MLKL (Abcam, ab184718; 1:1000), pMLKL (Abcam, ab196436; 1:1000), cleaved
597   caspase-3 (CST, 9664; 1:1000), β-actin (CST, 4970; 1:2000), or vinculin (Sigma-Aldrich, V9131;
598   1:1000). The membranes were incubated with HRP-conjugated anti-rabbit (CST, 7074; 1:1000) or
599   HRP-conjugated anti-mouse (CST, 7076; 1:1000) IgG secondary antibodies and visualized using
600   ECL Prime Western Blotting Detection Reagent (GE Healthcare) and ImageQuant LAS 4000 Mini
601   (FUJIFILM). The experiments were performed in biological duplicates or triplicates.

602

603   **Statistical analysis**
604   We used GraphPad Prism (GraphPad ver.8) for statistical analysis. The two groups were
605   analyzed using the two-tailed unpaired *t*-test. For multiple comparisons, the data were analyzed
606   using one-way analysis of variance (ANOVA), followed by Tukey's multiple comparisons test for
607   multiple comparisons or by Dunnett's multiple comparisons test. Time to tumor progression was
608   estimated using Kaplan–Meier curves and was statistically analyzed using the log-rank Mantel–
609   Cox test or the Gehan–Breslow–Wilcoxon test. Each data point represents the mean ± standard
610   deviation (SD) derived from at least three animals or biological replicates. *P*-values <0.05 were
611   considered statistically significant.

796   **Figure 1. Naked mole-rats (NMRs) do not develop tumors in response to two types of**
797   **chemical carcinogenesis induction.**
798   **A**, Schematic diagram for carcinogenesis induction by intramuscular (i.m.) injection of 1 mg 3-
799   methylcholanthrene (3MC) into the hind limb. **B**, Kaplan–Meier curves of tumor-free mice and
800   NMRs after i.m. injection of 1 mg 3MC. n = 9 animals per species. **C**, Gross appearance and
801   hematoxylin and eosin (HE) staining of a mouse tumor at 17 weeks and NMR muscle at 114
802   weeks after i.m. 3MC injection. Red arrows indicate injection sites. Scale bars: 1 cm (upper) and
803   50 μm (lower). **D**, Schematic diagram for carcinogenesis induction by subcutaneous (s.c.)

18

804   injection of 1 mg 3MC into the back skin. **E**, Kaplan–Meier curves of tumor-free NMRs after s.c.
805   injection of 1 mg 3MC. *n* = 5 animals. **F**, Gross appearance and HE staining of NMR back skin at
806   97 weeks after s.c. injection of 1 mg 3MC. The red arrowhead indicates the injection site. Scale
807   bars: 1 cm (gross) and 100 μm (HE). *n* = 5 animals. **G**, Schematic diagram for carcinogenesis
808   induction by 7,12-dimethylbenz[a]anthracene (DMBA)/12-O-tetradecanoylphorbol-13-acetate
809   (TPA) treatment on the back skin. **H**, Kaplan–Meier curves of tumor-free mice and NMRs after
810   starting DMBA/TPA treatment. *n* = 6 animals per species. **I**, Gross appearance and HE staining of
811   mouse papillomas at 20 weeks and NMR skin at 55 weeks after starting DMBA/TPA treatment.
812   Scale bars: 1 cm (upper) and 100 μm (lower). Inset is a higher magnification of NMR skin (scale
813   bar: 50 μm). Log-rank test for **B** and **H**.
814
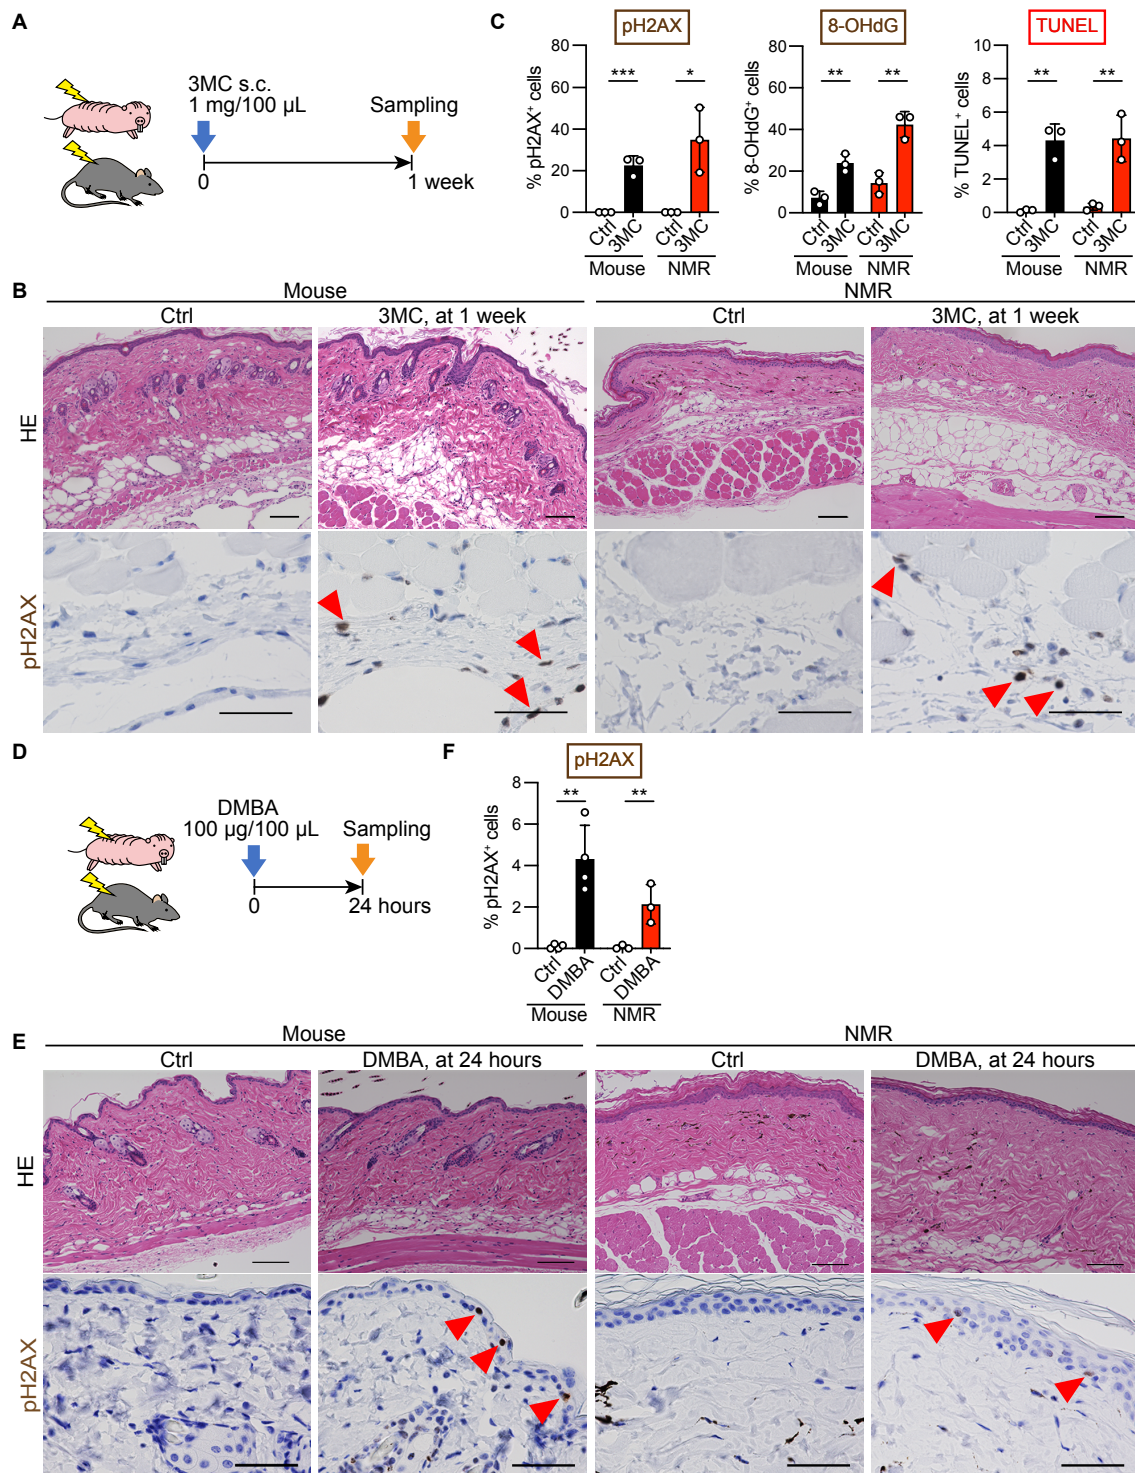

815
816 **Figure 2. DNA damage and cell death increase in NMRs upon administration of**
817 **carcinogens.**
818 **A**, Schematic diagram for investigating short-term responses to 3MC after subcutaneous (s.c.)
819 injection into the back skin. **B**, HE staining and immunohistochemical staining for phospho-
820 histone H2A.X (pH2AX, brown) of the skin of mice and NMRs at 1 week after s.c. injection of

821   3MC. Scale bars: 100 μm (HE) and 50 μm (pH2AX). Red arrowheads indicate positive cells. **C**,

822   Quantification of pH2AX-, 8-hydroxy-2′-deoxyguanosine (8-OHdG)-, and TUNEL-positive cells

823   after s.c. injection of 3MC. **D**, Schematic diagram for investigating short-term responses to DMBA

824   treatment on the back skin. **E**, HE staining and immunohistochemical staining of pH2AX (brown)

825   in the skin of mice and NMRs at 24 h after DMBA treatment. Scale bars: 100 μm (HE) and 50 μm

826   (pH2AX). Red arrowheads indicate positive cells. **F**, Quantification of pH2AX-positive cells at 24 h

827   after DMBA treatment. For quantification in **C** and **F**, data are presented as the mean ± SD of *n* =

828   3–4 animals. Unpaired *t*-test versus untreated control (Ctrl).

829
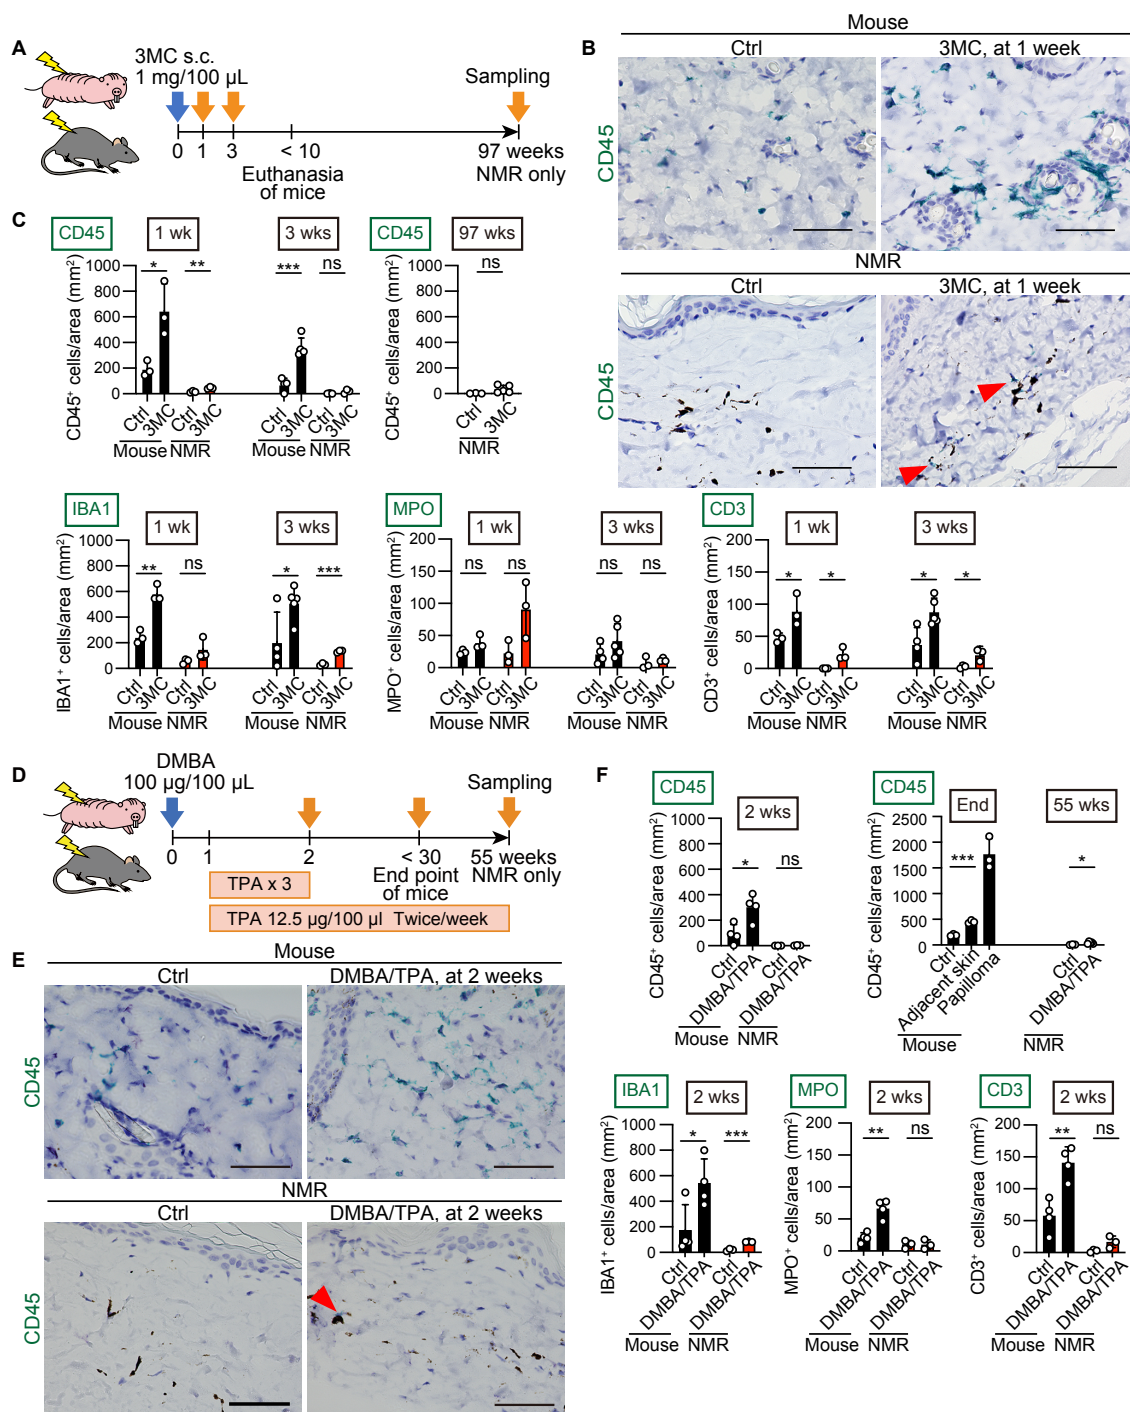

Figure 3. NMRs show attenuated infiltration of inflammatory immune cells into tissues upon administration of carcinogens.

A, Schematic diagram for investigating immune cell infiltration into the skin after a subcutaneous (s.c.) injection of 3MC. **B**, Immunohistochemical detection of CD45 (green)-positive cells in skin sections 1 week after s.c. injection of 3MC. Black dots are melanin pigments in NMR dermis. Scale bar: 50 μm. Red arrowheads show positive cells in NMRs. **C**, Quantification of CD45-, IBA1-, MPO-, and CD3-positive cells per area in skin sections at 1, 3, and 97 (only for CD45)

838   weeks after s.c. injection of 3MC. **D**, Schematic diagram for investigating immune cell infiltration
839   into the skin after exposure to DMBA/TPA. **E**, Immunohistochemical detection of CD45 (green)-
840   positive cells in skin sections at 2 weeks after exposure to DMBA/TPA. Black dots are melanin
841   pigments in NMR dermis. Scale bar: 50 μm. The red arrowhead shows a positive cell in NMRs. **F**,
842   Quantification of CD45-, IBA1-, MPO-, and CD3-positive cells per area in skin sections at 2 and
843   55 (only for CD45) weeks after exposure to DMBA/TPA. Mice were analyzed at the end point.
844   "Adjacent skin" is the no-papilloma region from DMBA/TPA-treated mouse skin. For quantification
845   in **C** and **F**, data are presented as the mean ± SD of n = 3–5 animals. Unpaired t-test versus
846   untreated control (Ctrl).
847
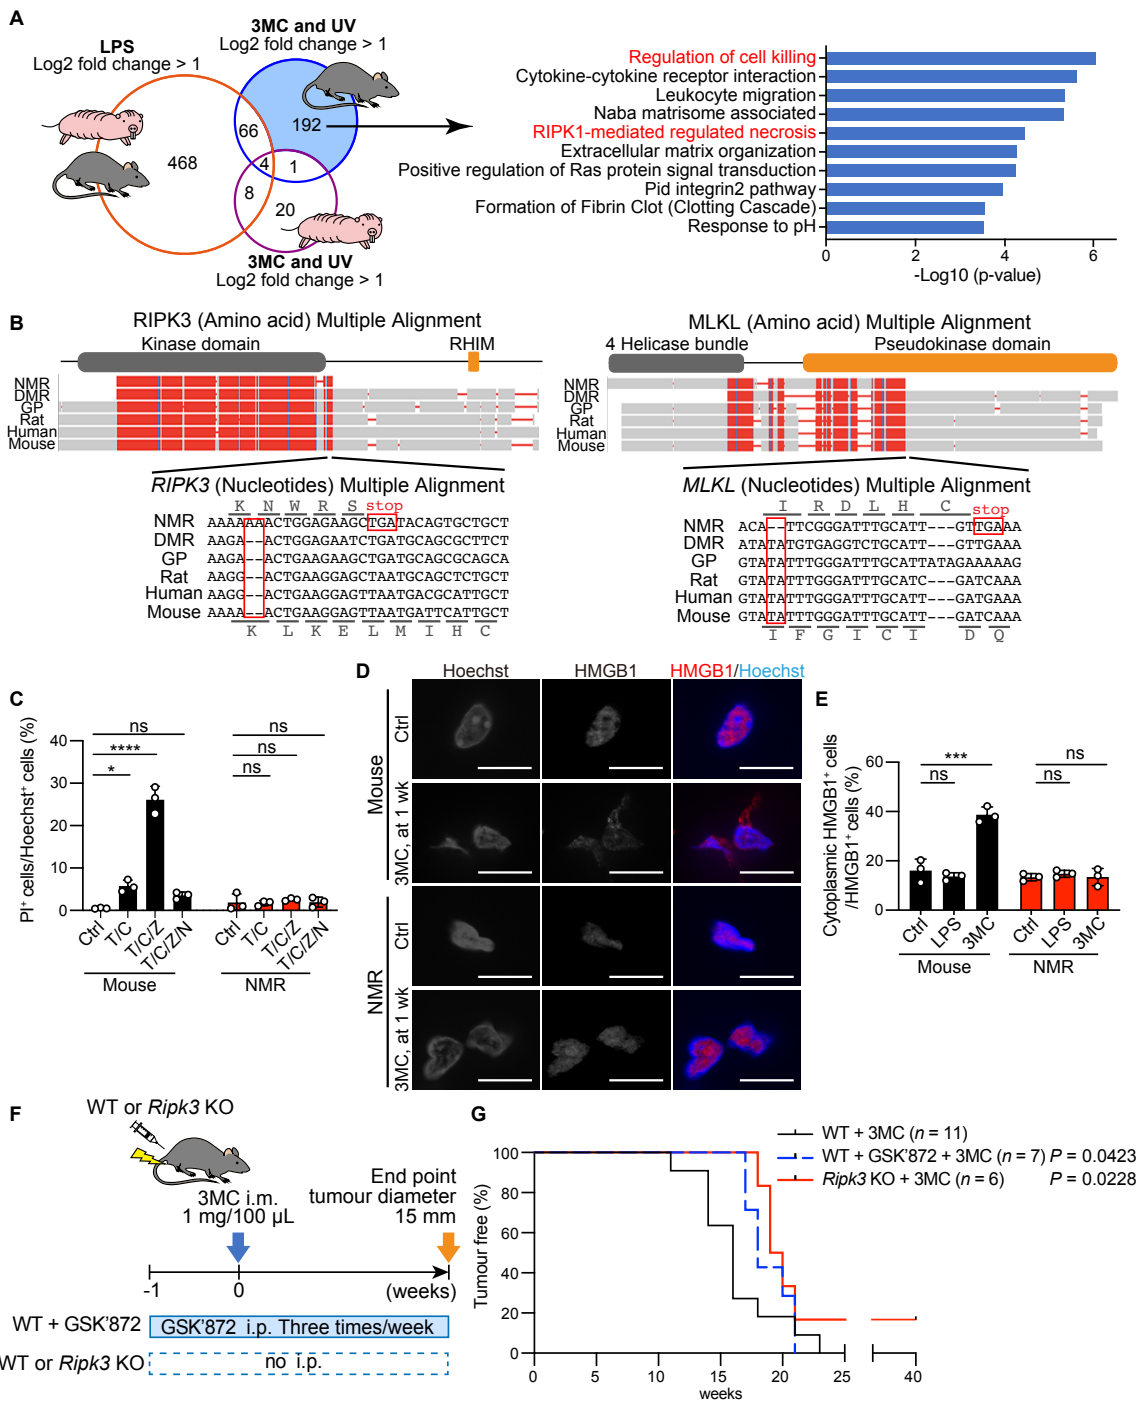

Figure 4. Loss of necroptosis regulators may contribute to an attenuated tissue inflammatory response and resistance to carcinogenesis in NMR individuals. A, Venn diagram showing the number of genes upregulated in both mouse and NMR skin upon lipopolysaccharide (LPS) treatment; genes upregulated specifically in mouse or NMR skin upon exposure to 3MC (1 week) and UV; and enriched pathways of 3MC-UV Mouse-DEGs. **B**, Multiple alignments of receptor-interacting kinase 3 (*RIPK3*) and mixed lineage kinase domain-like (*MLKL*) sequences from the NMR, Damaraland mole-rat (DMR), guinea pig (GP), rat, human, and mouse. Frame-shift mutations and premature stop codons in the NMR sequence are boxed. Reading

857   frames for the NMR and mouse sequences are indicated. The functional domains are shown
858   above the alignments. **C**, Cell death analysis in fibroblasts treated with a combination of TNF-α
859   (T), cycloheximide (C), z-VAD-fmk (Z), or Nec-1 (N). Data are presented as the mean ± SD of n =
860   3 independent experiments. **D**, Immunofluorescence staining of high mobility group box-1 protein
861   (HMGB1, red) in skin at 1 week after 3MC-injection. Nuclei: blue. Scale bar: 10 μm. **E**,
862   Quantification of cytoplasmic HMGB1 in skin after each treatment. Data are presented as the
863   mean ± SD of n = 3 animals for each species. One-way ANOVA with Tukey's multiple
864   comparison test for **C** and Dunnett's multiple comparisons test versus untreated control (Ctrl) for
865   **E**. **F**, Schematic diagram for carcinogenesis induction by intramuscular (i.m.) injection of 3MC
866   with intraperitoneal (i.p.) injection of GSK'872 in mice or i.m. injection of 3MC in *Ripk3* knockout
867   (KO) mice. **G**, Kaplan–Meier curves of tumor-free mice (n = 11 [for wild-type, WT], n = 7 [for
868   GSK'872], or n = 6 [for *Ripk3* KO] animals). P = 0.0423 for GSK'872 and P = 0.0228 for *Ripk3*
869   KO; Gehan–Breslow–Wilcoxon test.

25
