Abstract

Altered host-microbe interactions and increased intestinal permeability have been implicated in the pathogenesis of a range of diseases. However, the mechanisms by which gut microbes affect epithelial barrier integrity remain unclear. Few host-produced metabolites that protect against epithelial damage have been identified, and whether microbial metabolism of host factors alters intestinal barrier function is unknown. Here, we investigate the effects of bacterial metabolism of host-produced bile acid (BA) metabolites on epithelial barrier integrity. We observe that rats fed a choline-deficient, high-fat diet (CDAHFD) exhibit reduced abundance of host-produced conjugated BAs in the intestine at early timepoints coinciding with increased permeability. We show that in vitro, conjugated BAs protect gut epithelial monolayers from damage caused by bacterially produced unconjugated BAs through micelle formation. We then demonstrate that inhibition of BA deconjugation using a small molecule inhibitor of gut bacterial bile salt hydrolase (BSH) enzymes prevents development of pathologic intestinal permeability and hepatic inflammation in CDAHFD-fed rats. Finally, we show that the predominant conjugated BAs in humans protect against epithelial barrier disruption in vitro. Our study identifies a protective role for conjugated BAs in intestinal epithelial barrier function and suggests that rational manipulation of microbial BA metabolism could be leveraged to regulate gut barrier integrity.

Introduction

In health, the intestinal epithelium forms a dynamic and tightly sealed barrier that is selectively permeable (Buckley & Turner, 2018). However, under pathologic conditions, tight junctions can become disrupted with excessive leakage of dietary and bacterial antigens, including lipopolysaccharide (LPS), into the portal and systemic circulation, directly inducing inflammation in extraintestinal organs (Massier, Bluher, Kovacs, & Chakaroun, 2021). Emerging data have implicated increased intestinal permeability in the pathogenesis of a range of human diseases, including inflammatory bowel disease (IBD), liver disease, type 1 and type 2 diabetes, cardiovascular disease, and depression (Bosi et al., 2006; Chopyk & Grakoui, 2020; Damms-Machado et al., 2017; Ohlsson et al., 2019; Pasini et al., 2016). The gut microbial communities of these patients are altered compared to healthy subjects, and gut microbial imbalance has been proposed to contribute to the development of intestinal permeability (Albillos, de Gottardi, & Rescigno, 2020; Chakaroun, Massier, & Kovacs, 2020). However, specific host and microbial factors that result in the development of pathologic intestinal permeability remain unclear.

Bile acids (BAs) have been implicated as potential causal agents in the development of pathogenic intestinal permeability (Murakami, Tanabe, & Suzuki, 2016; Papillon, Frey, Ford, & Gayer, 2013). BAs are steroidal natural products that are present in high concentrations in the gut (~200 μM to 1 mM in the large intestine) (Hamilton et al., 2007). In the liver, host enzymes convert cholesterol into conjugated primary bile acids, which contain a steroidal core appended to taurine or glycine through an amide bond linkage (**Figure 1A**). These compounds act as digestive surfactants; in humans, these metabolites are stored in the gallbladder and secreted into the small intestine post-prandially in order to aid in the absorption of lipids and vitamins (de Aguiar Vallim, Tarling, & Edwards, 2013). In the lower GI tract, bacteria convert primary conjugated bile acids into unconjugated primary BAs through the action of bile salt hydrolase (BSH) enzymes (Ridlon, Harris, Bhowmik, Kang, & Hylemon, 2016). BSHs are expressed in a

3

63   broad range of human gut bacteria (Song et al., 2019) and have no mammalian homolog (Foley,

64   O'Flaherty, Barrangou, & Theriot, 2019). Bacterial enzymes then further chemically modify

65   primary BAs, producing unconjugated secondary BAs. Following enterohepatic recirculation,

66   these molecules can be converted to conjugated primary and secondary BAs in the liver and then

67   re-secreted into the gut (Ridlon et al., 2016).

68

69   Previous work has demonstrated that exposure of epithelial monolayers to certain hydrophobic

70   BAs, including unconjugated BAs, leads to increased intestinal permeability in vitro and may

71   contribute to the development of intestinal inflammation and disruption of intestinal homeostasis

72   in vivo (Raimondi et al., 2008; Sarathy et al., 2017). In animal models, long-term administration

73   of a high-fat diet has been shown to lead to increased intestinal permeability associated with an

74   enrichment of hydrophobic BAs in the intestinal BA pool (Gupta et al., 2020; Stenman, Holma,

75   Eggert, & Korpela, 2013; Stenman, Holma, & Korpela, 2012). While unconjugated BAs have been

76   shown to increase epithelial permeability, the role of conjugated BAs in epithelial permeability is

77   unclear, and it is not known whether bacterial BA deconjugation affects intestinal homeostasis in

78   vivo.

79

80   Considering the close physiological relationship between the gut and the liver, optimal intestinal

81   barrier function is crucial for liver homeostasis (Nicoletti et al., 2019). Disruption of intestinal

82   barrier integrity may accelerate the pathogenesis of liver disease (Chopyk & Grakoui, 2020). Here,

83   we observe that increased intestinal permeability is an early feature of liver disease in rats fed a

84   choline-deficient, L-amino acid defined, high-fat diet, an animal model of liver cirrhosis

85   accompanied by pathogenic intestinal barrier damage (Longo et al., 2020). We also observed a

86   significant reduction in the abundance of intestinal and portal venous conjugated BAs in

87   CDAHFD-treated rats at early timepoints. Hypothesizing that conjugated bile acids could protect

88   the intestinal barrier against chemical insults, we demonstrate that tauro-conjugated BAs

4

89 sequester unconjugated BAs into micelles. We then show that this sequestration of unconjugated

90 bile acids protects epithelial cells from damage and permeability in vitro. Furthermore, using a

91 small molecule inhibitor of bacterial BSHs that we recently developed (Adhikari et al., 2021;

92 Adhikari et al., 2020), we show that inhibition of BSH activity increases conjugated BA abundance

93 in vivo and prevents the development of increased intestinal permeability, hepatic steatosis, and

94 hepatic inflammation in diseased rats. Finally, we demonstrate that glyco-conjugated BAs, the

95 predominant BAs in humans, also protect against epithelial damage caused by unconjugated BAs

96 in vitro. Together, these data indicate that gut microbial enzymes interact with host metabolites to

97 affect intestinal barrier function.

98

99 **Results**

100 **CDAHFD-fed rats develop increased intestinal permeability prior to developing hepatic**

101 **inflammation**

102 To investigate the molecular mechanisms leading to the development of intestinal permeability in

103 the context of an animal model relevant to human disease, we utilized a choline-deficient, L-amino

104 acid defined, high-fat diet (CDAHFD) in rats. CDAHFD is an established rodent model of diet-

105 induced cirrhosis that is characterized by disrupted epithelial barrier integrity (Zhong, Zhou, Xu,

106 & Gao, 2020). Previous studies have also found choline deficiency to be associated with

107 development of non-alcoholic fatty liver disease (NAFLD) and NASH in humans (Corbin & Zeisel,

108 2012; Guerrerio et al., 2012). CDAHFD-fed rats developed cirrhosis in 12 weeks (Matsumoto et

109 al., 2013) while controls fed a high-fat diet with equivalent fat by weight developed microvesicular

110 steatosis without inflammation or fibrosis (**Figure S1A**). CDAHFD-fed rats gained less weight than

111 controls and exhibited significantly increased markers of hepatocellular injury, hepatic

112 hydroxyproline levels, and mRNA expression of fibrosis-related and inflammatory genes at 12

113 weeks post-diet intervention (**Figure S1B-C,** refer **Table S1** for all qPCR primer sequences).

114

115   To assess intestinal permeability, we measured portal lipopolysaccharide (LPS) in CDAHFD-fed

116   rats at 48 hours, 1 week, 6 weeks, and 12 weeks (**Figure 1A,B**). Remarkably, portal LPS levels

117   were higher in CDAHFD-fed rats compared to controls as early as 48 hours post-diet intervention

118   (**Figure 1C**), when markers of liver injury were not yet significantly elevated (**Figure S1C-E**).

119   Further, intestinal epithelium from CDAHFD-fed rats exhibited significantly increased

120   inflammation and epithelial hyperplasia at early time points (**Figure S1F**). These data suggest

121   that intestinal injury and permeability precede hepatic phenotypes in the CDAHFD model of liver

122   disease. To confirm these results, using a FITC-Dextran assay, we found that CDAHFD-fed rats

123   exhibited a significant increase in intestinal permeability compared to controls at 48 hours after

124   diet initiation (**Figure 1D**). We observed significantly increased membrane localization of ZO-1 in

125   intestinal epithelial cells of CDAHFD-fed rats at 48 hours that persisted after 1 week of diet (**Figure**

126   **1E**, **F**). Increased expression and plasma membrane localization of ZO-1 are indicative of

127   increased intestinal permeability (Guo, Wang, Liu, & Ye, 2018; Karczewski et al., 2010).

128   Moreover, treatment of gut epithelial cells with permeability agents results in dynamic changes in

129   ZO-1 subcellular localization, including recruitment to the plasma membrane (Guan et al., 2011;

130   Odenwald et al., 2017). As such, ZO-1 redistribution in the intestinal epithelium of CDAHFD-fed

131   rats is consistent with increased intestinal permeability. Importantly, at 48 hours, CDAHFD-fed

132   rats did not exhibit any evidence of hepatic inflammation compared to controls while inflammation

133   was apparent at 1 week post-dietary intervention (**Figure S1C-E**). Together, these results

134   demonstrate that intestinal permeability is an early feature of this animal model and precedes the

135   development of hepatic inflammation.

136

137   **Conjugated BAs are reduced in the cecum and portal veins of CDAHFD-fed rats at early**

138   **timepoints**

139   To assess whether changes in BAs are associated with increased intestinal permeability, we

140   performed intestinal and portal venous BA profiling in CDAHFD-fed and control rats using ultra-

141 high performance liquid chromatography-mass spectrometry (UPLC-MS). We observed a

142 significant decrease in the abundance of cecal and portal venous conjugated BAs in CDAHFD-

143 fed rats at 48 hours and 1 week after dietary intervention (**Figure 1G-H**). In particular, levels of

144 tauro-cholic acid (TCA) and tauro-alpha- and tauro-beta-muricholic acid (Tα/βMCA) were

145 decreased in both cecal contents and portal veins at both timepoints (**Figure S2-5)**. Total cecal

146 and portal venous BA concentrations were similar between the two groups at these early

147 timepoints (**Figure S2-5**). In addition, levels of the conjugated bile acids tauro-chenodeoxycholic

148 acid (TCDCA), tauro-deoxycholic acid (TDCA), and tauro-ursodeoxycholic acid (TUDCA) were

149 decreased and levels of the unconjugated BAs cholic acid (CA), chenodeoxycholic acid (CDCA),

150 α-muricholic acid (αMCA), and β-muricholic acid (βMCA) were increased in portal veins at the 1

151 week timepoint (**Figure S5**). These findings indicate that changes in cecal and portal venous BA

152 composition are associated with the onset of increased intestinal permeability in CDAHFD-fed

153 rats and suggest that these metabolites could play a causal role in development of gut barrier

154 damage.

155

156 Intestinal permeability and inflammation are regulated in part by the BA-sensing farnesoid X

157 receptor (FXR), which has been linked to NAFLD/NASH pathogenesis (Arab, Karpen, Dawson,

158 Arrese, & Trauner, 2017; Li et al., 2013). In addition, FXR signaling modulates a tight negative

159 feedback loop that controls BA synthesis in the liver (Fiorucci & Distrutti, 2015). At 48 hours after

160 dietary intervention, ileal *Fgf15* expression was similar in both groups when multiple lines of

161 evidence for increased intestinal permeability were already observed in CDAHFD-fed animals

162 (**Figure S6A**). Expression of BA synthesis and conjugation enzymes were not significantly

163 affected in CDAHFD-fed rats at 48 hours of diet **(Figure S6B)**. Expression levels of BA transporter

164 proteins were also unaffected in CDAHFD-fed rats compared to controls **(Figure S6C)**. We found

165 that cecal BSH activity in CDAHFD rats was significantly increased at 48 hours compared to

166 control rats (**Figure S6D**) (Adhikari et al., 2020). These data suggest that the decrease in

167   conjugated BAs in CDAHFD-fed rats was driven at least in part by an increase in BA

168   deconjugation by gut microbes. Together, our findings suggest that FXR-independent

169   mechanisms are responsible for the earliest events that establish intestinal barrier dysfunction in

170   this animal model of pathogenic intestinal permeability.

171

172   **In vivo BA compositions reflect increased intestinal permeability as disease progresses**

173   UPLC-MS analysis revealed significant decreases in cecal unconjugated BAs in CDAHFD-fed

174   rats at 6 weeks (e.g., αMCA, LCA, DCA, UDCA) and in unconjugated, conjugated, and total BAs

175   at 12 weeks (e.g., CA, αMCA, βMCA, LCA, DCA, UDCA, TDCA, tauro-omega-muricholic acid

176   (TωMCA), TUDCA) compared to control animals (**Figure S7,8)**. Interestingly, at the same

177   timepoints, portal venous BA profiling revealed the inverse finding, with significantly higher

178   concentrations of total and unconjugated BAs (e.g., CA, CDCA, αMCA, βMCA) in CDAHFD-fed

179   rats compared to controls (**Figure S9,10)**. No significant differences were observed in the

180   expression of genes involved in BA synthesis (*Cyp7a1, Cyp8b1, Cyp27a1*) or transport (*Asbt*,

181   *Osta/Ostb*) (**Figure S11A,B**), indicating that the observed changes are unlikely to be the result of

182   decreased BA synthesis or increased BA transport. These findings are consistent with the

183   observation that CDAHFD-treated rats exhibit epithelial barrier damage and suggest that as

184   disease progresses, increased intestinal permeability results in leakage of intestinal BAs into

185   portal circulation.

186

187   **Conjugated BAs protect intestinal epithelial monolayers from unconjugated BA-mediated**

188   **damage in vitro**

189   Based on our in vivo observations, we hypothesized that groups of conjugated or unconjugated

190   BAs could be causally contributing to epithelial layer damage. To test this hypothesis, we utilized

191   Caco-2 cells in transwell inserts as an in vitro model system. Once differentiated, these cells form

192   a polarized monolayer that mimics the intestinal epithelium, and this system has been previously

193   used to study the effect of metabolites on gut layer integrity (Scott, Fu, & Chang, 2020). Gut

194   permeability was assayed by measuring FITC-Dextran (4 kDa) permeability through the

195   monolayer and quantifying fluorescence in the basolateral chamber (Chaudhari, Harris, et al.,

196   2021). We found that cecal extracts isolated from CDAHFD-fed rats at 48 hours and 1 week

197   induced increased permeability compared to cecal extracts from control rats (**Figure 2A**). These

198   findings demonstrate that intestinal contents from CDAHFD-fed rats induce epithelial barrier

199   permeability at early timepoints.

200

201   To test whether cecal BAs specifically induce epithelial permeability, we generated reconstituted

202   pools of BAs that mimic the average physiological concentrations observed in rat ceca and tested

203   their ability to induce permeability in Caco-2 monolayers in vitro. The 48 hour CDAHFD total BA

204   pool induced significantly higher permeability than the DMSO control (**Figure 2B**). Interestingly,

205   while the unconjugated BA pool alone induced a significant increase in permeability, the

206   conjugated BA pool did not damage the monolayer barrier integrity. Remarkably, at later time

207   points (1, 6, 12 weeks), the addition of conjugated BAs to unconjugated BAs mitigated the severity

208   of epithelial permeability compared to unconjugated BAs alone (**Figure 2B**).

209

210   We next hypothesized that cecal conjugated BAs protect against the disruption of the epithelial

211   integrity. To test this hypothesis, we generated equimolar pools of the predominant cecal BAs

212   that we detected in vivo. We treated differentiated Caco-2 monolayers with increasing

213   concentrations of either (1) unconjugated BAs (βMCA, CA, DCA, UDCA, CDCA); (2) conjugated

214   BAs (TβMCA, TCA, TDCA, TUDCA, TCDCA) or (3) combined BA pools, followed by the

215   permeability assessment (**Figure 2C**).

216

217   At physiological concentrations of BAs in CDAHFD-fed rat cecal contents (~1000-4000 μM),

218   epithelial monolayer integrity was compromised after addition of unconjugated BAs but damage

9

219 was prevented by addition of an equimolar concentration of conjugated BAs (**Figure 2D,**

220 **S2,3,7,8**). Conjugated BAs alone did not disrupt monolayer integrity at any concentrations tested.

221 Similarly, while unconjugated BAs were toxic to cells, equimolar addition of conjugated BAs

222 abrogated this effect (**Figure 2E**). Visualization of Caco-2 monolayers by hematoxylin and eosin

223 staining further confirmed the toxic effects of unconjugated BAs were largely rescued by addition

224 of conjugated BAs (**Figure 2F**). Finally, to assess the integrity of tight junctions in the epithelial

225 monolayers, we performed transmission electron microscopy (TEM) on Caco-2 epithelial

226 monolayers exposed to the above BA groups. We identified dilatations in the tight junctions of

227 Caco-2 cells exposed to unconjugated BAs alone not present in cells exposed to conjugated BAs

228 alone or to a combination of both (**Figure 2G, Figure S12**). These tight junction dilatations have

229 been observed in ileal enterocytes of Crohn's disease patients and correlate with increased

230 permeability (Soderholm et al., 2002). Together, these results demonstrate that while

231 unconjugated BAs damage epithelial layers, conjugated BAs protect against intestinal epithelial

232 damage and permeability in vitro.

233

234 **Conjugated BAs sequester unconjugated BAs through the formation of micelles**

235 We next sought to determine the mechanism by which conjugated BAs protect intestinal epithelial

236 monolayers from unconjugated BA-mediated permeability in vitro. BAs are detergents and

237 effectively solubilize fats and vitamins by forming micelles in the intestine (Hofmann, 1963). We

238 hypothesized that when combined, conjugated BAs form micelles with unconjugated BAs,

239 sequestering unconjugated BAs away from the epithelial cells. To test this hypothesis, we

240 assessed the critical micelle concentration (CMC) of these BA populations using a fluorescent

241 probe (Fluksman & Benny, 2019). Unconjugated BAs are expected to have a higher CMC

242 compared to conjugated BAs (Pavlovic et al., 2018). If micelles formed after combining

243 unconjugated and conjugated BA populations, we would expect the CMC of the combined

244 populations to be lower than that seen with unconjugated BAs alone. Consistent with this

245   hypothesis, the combined pool CMC was 4.2 mM while the unconjugated and conjugated BA pool

246   CMCs were 6.7 mM and 4.0 mM, respectively (**Figure 3A**). The addition of 80 mM urea prevented

247   micelle formation as previously described (**Figure 3A**) (Hofmann, 1963). We also performed direct

248   visualization of micelles using negative staining-electron microscopy. At 5 mM concentration, no

249   micelles were visualized in the unconjugated BA pool while micelles were seen in the conjugated

250   BA pool, consistent with our CMC determinations and total cecal BA quantification in CDAHFD-

251   fed rats at the 48 hour time point (**Figure 3B, S2**). Combining BA pools resulted in larger micelles,

252   while urea prevented micelle formation entirely. Thus, in the presence of conjugated BAs,

253   unconjugated BAs are sequestered in micelles.

254

255   To investigate whether the protective effects of conjugated BAs are micelle-dependent, we tested

256   whether BA pools induce intestinal permeability in the presence of 80 mM urea, a concentration

257   that prevents micelle formation (**Figure 3A-B**) without inducing toxicity in Caco-2 cells (**Figure**

258   **3C**). Notably, addition of urea resulted in loss of conjugated BA-mediated protection of epithelial

259   barrier integrity and cell viability (**Figure 3D-F**). We also exposed Caco-2 monolayers to combined

260   BA pools in the presence or absence of urea and quantified the amount of unconjugated BAs that

261   passed through the monolayer into the basolateral chamber by UPLC-MS. We observed

262   significantly increased amounts of unconjugated BAs in the basolateral chamber in the presence

263   of urea, providing further evidence that micelle formation prevents epithelial damage and

264   permeability (**Figure 3G**). Together, our data provides evidence that unconjugated BAs lead to

265   increased permeability across an intestinal epithelial monolayer by inducing cytotoxic effects.

266   Further, these effects are prevented by the addition of conjugated BAs, which form BA micelles

267   with unconjugated BAs in vitro (**Figure 3H**).

268

269   **BSH inhibition by AAA-10 prevents altered intestinal permeability and hepatic**

270   **inflammation in CDAHFD-fed rats**

271   Because conjugated BAs appear to protect against intestinal epithelial damage, we hypothesized

272   that a decrease in microbial BA deconjugation by BSH might attenuate intestinal permeability in

273   CDAHFD-fed rats. We recently reported the development of a covalent, gut-restricted, small

274   molecule inhibitor of gut bacterial BSHs, AAA-10, a compound that effectively inhibits BSH activity

275   and increases the abundance of conjugated BAs in vivo (**Figure 4A)** (Adhikari et al., 2021). We

276   thus hypothesized that treatment of CDAHFD-fed rats with AAA-10 would prevent increased

277   intestinal permeability. A dose of 10 mg/kg AAA-10 or vehicle control was administered via

278   gavage twice a day for 7 days to CDAHFD-fed rats (**Figure 4B)**. AAA-10 administration led to

279   ~20-30 μM AAA-10 in cecal contents 48 hours and 1 week post-gavage (**Figure 4C**). No AAA-10

280   was detected in peripheral blood (**Figure S13A**), a finding that is consistent with our previous

281   results (Adhikari et al., 2021) and indicates that this BSH inhibitor exhibits low systemic exposure.

282   We found that AAA-10 reduced cecal BSH activity of CDAHFD-fed rats (**Figure 4D**) and

283   significantly increased both the abundance of conjugated BAs as a group (**Figure 4E**) and the

284   concentrations of individual conjugated BAs (**Figure S14**) by 1 week. Notably, we observed

285   significant decreases in levels of portal venous LPS suggestive of increased intestinal barrier

286   function in AAA-10-treated rats compared to vehicle-treated animals (**Figure 4F**). Furthermore,

287   we observed normalization of ZO-1 localization and expression, suggesting that AAA-10

288   treatment prevented the development of intestinal permeability in CDAHFD-fed rats (**Figure 4G**).

289

290   As intestinal permeability has been linked to translocation of intestinal products that further

291   exacerbate hepatic inflammation (Chopyk & Grakoui, 2020), we evaluated the impact of 8 day

292   AAA-10 treatment on liver phenotypes (**Figure 5A**). Consistent with our previous results, we found

293   that the BA pool shifted toward conjugated BAs in AAA-10-treated compared to control-treated

294   rats (**Figure S15**). Mild weight loss was observed in the AAA-10-treated animals (**Figure S16A**),

295   consistent with our previous report that genetic removal of bacterial BSH causes altered metabolic

296   phenotypes including reduced weight gain on a high fat diet (Yao et al., 2018). We did not observe

297 significant weight loss in AAA-10-treated rats in the 7 day experiment (**Figure S13B**), and we

298 observed similar changes in ZO-1 localization and expression in both experiments (**Figure 4G,**

299 **Figure S16B**), suggesting that AAA-10-mediated protection against intestinal permeability

300 occurred independent of weight loss. We also assessed the effect of AAA-10 or vehicle treatment

301 on normal chow-fed rats and found no significant differences between the groups in liver or kidney

302 function, body weight, or caloric intake (**Figure S17**), suggesting that AAA-10 itself was non-toxic

303 and that differences between groups are directly related to changes in intestinal BA composition.

304

305 We observed substantial histologic improvements in AAA-10-treated rats compared to vehicle-

306 treated controls. Specifically, AAA-10-treated rats exhibited significantly less hepatic steatosis,

307 lobular inflammation, and hepatocyte ballooning (**Figure 5B,C**). Consistent with these results, we

308 observed significant decreases in serum measures of hepatic inflammation including alanine

309 transaminase (ALT), aspartate transaminase (AST), and alkaline phosphatase (ALP) in AAA-10-

310 treated animals (**Figure 5D**). Finally, we observed decreased expression of pro-inflammatory and

311 pro-fibrotic genes in treated rats (**Figure 5E-F**). Together, our findings demonstrate that treatment

312 with the gut-restricted BSH inhibitor AAA-10 prevents the development of intestinal barrier

313 dysfunction and liver damage in CDAHFD-fed rats.

314

315 **Glyco-conjugated BAs form protective micelles in vitro**

316 While rodents possess only tauro-conjugated BAs, humans have a mixture of glyco- and tauro-

317 conjugated BAs, with the former dominating the pool in a ratio of 3:1 (**Figure 6A**) (Ridlon et al.,

318 2016). Further, microbial BSHs in the human intestine hydrolyze glyco-conjugated BAs to their

319 unconjugated forms (Ridlon et al., 2016). In order to test whether glyco-conjugated BAs are also

320 capable of forming micelles to sequester damaging unconjugated BAs, we determined critical

321 micelle concentrations (CMCs) of these BA populations as described above (**Figure 3A, B**). We

322 used an equimolar mix of (1) glyco-conjugated BAs (GCA, GDCA, GUDCA, GCDCA) or (2)

13

323　combined BA pools containing the same unconjugated BAs as used above (βMCA, CA, DCA,

324　UDCA, CDCA). Glyco-conjugated BAs exhibited a lower CMC than tauro-conjugated BAs (3.64

325　mM compared to 4.0 mM, respectively) (**Figure 6B, 3A**). Consistent with this observation and our

326　previous results, the CMC of the combined pool with glyco-conjugated BAs was 3.60 mM, while

327　the CMC of the combined pool of tauro-conjugated BAs was 4.2 mM (**Figure 6B, 3A**). We also

328　performed direct visualization of micelles using negative staining-electron microscopy. At 5 mM

329　concentration, no micelles were visible in the unconjugated BA pool while micelles were observed

330　in the glyco-conjugated and combined BA pools, consistent with our CMC determinations (**Figure**

331　**6C**). Together, these results suggest that glyco-conjugated BAs form micelles with unconjugated

332　BA species with equal to or greater efficiency than tauro-conjugated BAs.

333

334　Next, we sought to determine whether glyco-conjugated BAs would also protect the intestinal

335　epithelium from the damaging effects of unconjugated BAs. Using transwell-differentiated Caco-

336　2 cells, we found that unconjugated BA-induced epithelial monolayer damage was prevented by

337　addition of an equimolar concentration of glyco-conjugated BAs (**Figure 6D, E**). Glyco-conjugated

338　BAs alone did not disrupt monolayer integrity at any concentrations tested (**Figure 6E**). Similarly,

339　while unconjugated BAs were toxic to cells, equimolar addition of glyco-conjugated BAs

340　abrogated this effect (**Figure 6F**). Visualization of Caco-2 monolayers by hematoxylin and eosin

341　staining further confirmed that the toxic effects of unconjugated BAs were largely prevented by

342　addition of glyco-conjugated BAs (**Figure 6G**). Together, these results suggest that the

343　predominant human-derived glyco-conjugated BAs are also capable of sequestering

344　unconjugated BAs in micelles and protecting against epithelial permeability.

14

Discussion

In this study, we show that the onset of intestinal permeability is associated with decreased intestinal and portal conjugated BA abundance in a diet-induced animal model of intestinal barrier and liver damage. Furthermore, we demonstrate a mechanism by which conjugated BAs protect intestinal epithelial barriers from damage in vitro via the sequestration of unconjugated BAs in micelles. We then demonstrate that inhibition of gut bacterial BSH activity increases the abundance of cecal conjugated BAs and prevents the development of intestinal barrier dysfunction and liver inflammation in vivo. Finally, we show that both tauro-conjugated BAs and glyco-conjugated BAs protect against unconjugated BA-induced epithelial barrier damage in vitro. Because glyco- and tauro-conjugated BAs are the two conjugated BA forms found in humans, our data suggest that conjugated BAs could be protective in the human gut.

The CDAHFD-fed rat model we utilized here to investigate pathogenic intestinal permeability is a rodent model of chronic liver disease, including NAFLD and NASH progression (Longo et al., 2020). Gut dysbiosis is a central feature of human NAFLD/NASH and has been proposed to contribute to the development of these conditions (Boursier et al., 2016; Loomba et al., 2019). Likewise, changes in serum BA profiles have been reported to correlate with disease severity in NAFLD/NASH patients (Mouzaki et al., 2016; Nimer et al., 2020; Puri et al., 2018). However, causal connections between gut bacteria, bile acid metabolism, and NAFLD/NASH in humans have not yet been established. Our data raise the possibility that bacterial BA deconjugation may be causally contributing to NAFLD/NASH progression. Indeed, we observed higher levels of BSH activity in CDAHFD-treated rats compared to control animals. Future analyses will help uncover whether correlations exist between fecal BA levels, BSH activity, and disease severity in human patients. In addition, further studies in different animal models of pathogenic intestinal permeability will reveal whether pharmacological BSH inhibition can prevent or ameliorate gut barrier damage. Nonetheless, the finding that BSH inhibition prevents intestinal permeability and

15

371   liver damage in choline-deficient high fat diet-fed rodents, ~~a clinically relevant~~ a diet-induced

372   model of liver cirrhosis, suggests that modulating the in vivo BA pool by selective targeting of the

373   gut microbiota could be investigated as a treatment path for diseases characterized by intestinal

374   barrier disruption.

375

376   While intestinal barrier function has been implicated in the pathogenesis of a variety of diseases,

377   the molecular mechanisms that trigger or protect against intestinal permeability defects are

378   incompletely defined (Gupta et al., 2020). It has been shown that hydrophilic BAs, including

379   conjugated BAs, protect against cytotoxicity induced by hydrophobic bile acids, including many

380   unconjugated species (Araki et al., 2003; Di Ciaula et al., 2017; Hegyi, Maleth, Walters, Hofmann,

381   & Keely, 2018). However, prior to our work, the connection between the efficiency of micelle

382   formation by conjugated BAs and their ability to protect against unconjugated BA-induced

383   epithelial barrier damage had not been established. Here, we demonstrate that conjugated BAs

384   form micelles with unconjugated BAs at physiologically relevant concentrations in vitro. Micelle

385   formation leads to sequestration of hydrophobic, unconjugated BAs away from epithelial cells and

386   prevents cell death and tight junction dysfunction. These data demonstrate that distinct classes

387   of BAs elicit differential effects on intestinal epithelial permeability and delineate a mechanism by

388   which one of these classes, conjugated BAs, protects against epithelial damage in vitro. Whether

389   this mechanism is operable in vivo, however, is not yet known. Cholesterol, phospholipids, and

390   lipid hydrolysis products form mixed micelles with bile acids in bile and in the intestine (Hofmann,

391   1999). The presence of these other compounds could alter micelle formation and thus the

392   protective effects of conjugated BAs observed in vitro. To our knowledge, there are currently no

393   selective means of preventing micelle formation in vivo. Nonetheless, by inhibiting BSH activity

394   using AAA-10, we selectively shifted the in vivo BA pool toward conjugated BAs. These

395   experiments showed that, consistent with our in vitro data, conjugated BAs protect against

396   epithelial barrier damage in vivo.

397

398   The treatment of CDAHFD-fed rats with a gut-restricted BSH inhibitor not only prevented intestinal

399   permeability but also protected against the development of hepatic inflammation and steatosis.

400   The prevention of liver damage is likely multifactorial, and effects including decreased

401   translocation of bacterial products such as LPS as well as mild weight loss may contribute. The

402   weight loss observed is likely a result of BSH-dependent metabolic changes as we have

403   previously reported (Yao et al., 2018). Interestingly, germ-free mice, which lack BSH and therefore

404   have high levels of intestinal conjugated BAs, are resistant to development of hepatic steatosis

405   (Brandl & Schnabl, 2017). Moreover, colonization of germ-free mice on a HFD with BSH-

406   containing bacteria induces hepatic steatosis, a phenotype that can be prevented by deletion of

407   BSH (Yao et al., 2018). Our results here demonstrate that shifting the in vivo BA pool to enrich

408   for conjugated BAs can not only prevent pathogenic intestinal permeability but can also prevent

409   fat deposition and inflammation in the host liver.

410

411   Overall, our findings link changes in the intestinal BA pool, specifically conjugated BAs, with

412   maintenance of the intestinal epithelial barrier in vivo. Our study also reveals that bacterial BSH

413   enzymes regulate metabolites that control gut barrier integrity, thereby providing a potential

414   mechanistic link between the microbiome and the development of pathogenic intestinal

415   permeability. Our findings suggest that strategies that reduce BSH activity in the human gut

416   microbiome could be developed as novel paradigms to treat intestinal barrier dysfunction.

417

418   **Materials and Methods**

419

420   **Animals**. 8-week old Wistar rats were purchased from Charles River Laboratories (Wilmington,

421   MA) and housed in a specific pathogen-free environment (maximum four per cage). After 10 days

422   of acclimation, rats were initiated on either a control high-fat diet (60 kcal% fat; Research Diets

423   D12492) or CDAHFD (L-amino acid diet with 60 kcal% fat with 0.1% methionine without added

424   choline; Research Diets A06071302) *ad libitum* for either 48 hours or 1 week (either 7 or 8 days).

425   At time of sacrifice, rats were anesthetized using 100 mg/kg of ketamine and 10 mg/kg of xylazine

426   intraperitoneally followed by portal vein blood draw and terminal cardiac puncture.

427

428   **In vivo intestinal permeability assay**. Intestinal permeability was assessed by in vivo

429   fluorescein isothiocyanate (FITC)-dextran (FD4; Sigma-Aldrich, St. Louis, MO) permeability assay

430   as described previously (Woting & Blaut, 2018). Rats were fasted for 4 hours and then had blood

431   collected via tail vein puncture to assess background fluorescence. Rats were then gavaged with

432   0.4 mg/g body weight FITC-dextran 4kDa solution and blood was collected by terminal cardiac

433   puncture. Fluorescence intensity in the serum determined at 530 nm with excitation at 485 nm.

434   Relative fluorescence units determined by subtracting the PBS blank fluorescence from all

435   samples and then subtracting the pre-gavage fluorescence from the post-gavage fluorescence.

436   FITC-dextran concentrations were determined from a standard curve generated by serial dilutions

437   of FITC-dextran.

438

439   **AAA-10 treatment.** After initiation of CDAHFD diet, rats were split into two groups and were

440   gavaged twice a day with either 10 mg/kg of AAA-10 dissolved in 5% Captisol (Ligand, San Diego,

441   CA) and 5% DMSO in PBS or an equal volume of 5% Captisol and 5% DMSO in PBS.

442

443   **RNA extraction and RT-qPCR**. Total RNA was extracted from liver tissue using TRizol

444   (Invitrogen) according to the manufacturer's instructions and subsequently treated with DNase I

445   (Promega). cDNA was generated using the RevertAid First Strand cDNA Synthesis kit according

446   to manufacturer's instructions (Thermo Fisher) and RT-qPCR was performed using the Power

447   SYBR Green Master Mix Kit (Thermo Fisher). Expression of *GAPDH* was used to standardize the

448   samples, and the results are expressed as a ratio relative to control. The genes for which

449 expression was determined and the primer sequences used in this study can be found in

450 **Supplementary Table 1**.

451

452 **Serum processing**. A cardiac terminal blood withdrawal was performed at the time of sacrifice.

453 Blood was allowed to clot for 2 hours at room temperature before centrifugation at 2,000 rpm for

454 10 minutes at 4°C. Serum was isolated and stored at -80°C. Biochemical markers of liver injury

455 were measured, including alkaline phosphatase, alanine aminotransferase, and aspartate

456 aminotransferase (DRI-CHEM 4000 Analyzer, Heska).

457

458 **Histology and immunofluorescence**. Formalin fixed paraffin embedded (FFPE) liver and ileum

459 tissue were sectioned at a thickness of 4 um. Slides were stained with hematoxylin and eosin at

460 the MGH Cytopathology Core. Slides were stained with Sirius Red for fibrosis staging. Slides

461 were blindly reviewed by a blinded pathologist to grade steatosis, inflammation, and fibrosis, using

462 criteria modeled on human NASH histologic scoring systems. Similarly, for intestine, slides were

463 evaluated for intestinal inflammation, epithelial hyperplasia, and goblet cell loss. For

464 immunofluorescence, sections were stained for ZO-1 (Abcam, Cambridge, MA) with detection by

465 appropriate secondary antibodies labeled with Alexa488 according to the manufacturer's

466 instructions. Hydroxyproline was quantified by high-performance liquid chromatography analysis

467 as previously described (Hutson, Crawford, & Sorkness, 2003).

468

469 For ZO-1 staining intensity measurement, images were processed and analyzed with Adobe

470 Photoshop CC software. Matched images were taken with the same exposure and were

471 processed and analyzed identically. The two-dimensional image intensities of ZO-1 fluorescence

472 (in pixels) of n=10 randomly selected cells in micrographs from each condition were measured

473 using Photoshop software (Adobe) and plotted in GraphPad Prism.

474

475 **LPS measurement assay**. Bacterial endotoxin measurement in portal serum samples was

476 performed using the Lonza Pyrogent turbidometric LAL assay kit (Lonza, N383) according to

477 manufacturer's instructions. Briefly, serial dilutions of prepared serum samples were made using

478 the LAL reagent water provided in the kit, followed by incubation for 15 min at 37ºC. Samples

479 were then mixed with the reconstituted Pyrogent reagent from the kit, followed by kinetic

480 turbidometric analyses in a SpectraMax M5 plate reader (Molecular Devices, San Jose, CA) at

481 the ICCB-Longwood Screening Facility at HMS. LPS amount in samples was deduced using

482 standard curves generated from stock provided in the kit and linear regression calculation.

483

484 **Bile acid analysis**. BA analyses were performed using a previously reported method (Yao et al.,

485 2018).

486 Reagents. Stock solutions of all bile acids were prepared by dissolving compounds in molecular

487 biology grade DMSO (VWR International). These solutions were used to establish standard

488 curves. HPLC grade solvents were used for preparing and running UPLC-MS samples.

489 Extraction. Rat cecal and human fecal samples (approximately 50 mg each) were collected in

490 pre-weighed lysis tubes. The lysis tubes contained ceramic beads to allow for homogenization

491 (Precellys lysing kit tough micro-organism lysing VK05 tubes for rat cecal and human fecal

492 samples; Bertin technologies, Montigny-le-Bretonneux, France). 400 μL of methanol (MeOH) was

493 added to rat cecal and human feces and the tubes were homogenized in a MagNA Lyser (6000

494 speed for 90 s*2, 7000 speed for 60 s). For portal venous samples, serum (100 μL) was collected

495 in eppendorf tubes, followed by addition of 100 μL MeOH. Samples were vortexed and frozen at

496 -20°C until further analysis. Cell culture media was diluted 1:1 in MeOH. All MeOH-extracted

497 samples were centrifuged at 4°C for 30 min at 15,000 rpm. The supernatant was diluted 1:1 in

498 50% MeOH/water and centrifuged again at 4°C for 30 min at 15000 rpm. The supernatant was

499 transferred into mass spec vials and injected into the UPLC-MS. Total bile acids were then

500 calculated by adding all detected and measured bile acids. The limits of detection for individual

20

501   bile acids have been described previously (Chaudhari, Harris, et al., 2021; Chaudhari, Luo, et al.,

502   2021; Yao et al., 2018).

503

504   **Caco-2 cell culture and differentiation**. Caco-2 cells were obtained from American Type Culture

505   Collection (Manassas, VA). Cells were maintained in Minimum Essential Medium (MEM) with

506   GlutaMAX and Earle's Salts (Gibco, Life Technologies, UK). Cell culture media were

507   supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin, and 100 µg/mL

508   streptomycin (GenClone). Cells were grown in FBS- and antibiotic-supplemented 'complete'

509   media at 37°C in an atmosphere of 5% CO_2. Undifferentiated Caco-2 cells were seeded in 24-

510   well plate transwells (0.4 µM pore size, Costar) at 200,000 cells per transwell. Media was changed

511   on days 4, 8, 12, 16, and 18 to differentiate Caco-2 cells in vitro (Lea, 2015). On day 21, fully

512   differentiated and polarized cells were used for permeability and toxicity assays.

513

514   **H&E staining and light microscopy of transwells**. Differentiated Caco-2 cells in transwells

515   were stained with H&E stain (Abcam, ab245880) according to manufacturer's instructions. Briefly,

516   transwells were washed with PBS, followed by staining with hematoxylin for 5 min. Transwells ere

517   rinsed in twice in dH_2O to remove excess stain, followed by addition of bluing reagent and

518   incubation for 10-15 sec. Two rinses in dH_2O was performed prior to addition of ethanol (Sigma)

519   to remove excess reagent. Ethanol was removed, and adequate Eosin was added for 2-3 min for

520   the counter stain. Transwells were dehydrated in ethanol 2-3 times, dried, and imaged using an

521   Evos XL Core microscope (Invitrogen) attached to camera at the ICCB-Longwood Screening

522   Facility at HMS. Cells were imaged from the top, and all images were taken at the same

523   magnification and light intensity. For each treatment, n=2 transwells were imaged, providing 4

524   images per transwell. Representative images are shown in **Figures 2, 3,** and **6**.

525

526 **In vitro bile acid treatments**. Caco-2 cells (undifferentiated in 96-well plates or day 21 to 25 of

527 differentiation in transwells) were treated with bile acid mixtures for 12-16 hours prior to assays.

528 Diluted stocks of bile acid standards or undiluted methanol-extracted cecal contents were added

529 in complete media. Transcytosis of bile acids was measured by drying basolateral media in a

530 speed vac followed by resuspending media in 1:1 methanol/water, transferred into mass

531 spectrometry vials and injected onto the ultra-high performance liquid chromatography-mass

532 spectrometer (UPLC-MS).

533

534 **Caco-2 permeability assay**. Epithelial integrity by FITC-dextran permeability assay was

535 performed as described previously (Chaudhari, Harris, et al., 2021). Briefly, differentiated Caco-

536 2 epithelial integrity was assayed by measuring passive diffusion of 4 kDa FITC-Dextran (Sigma

537 Aldrich) added at a concentration of 5 μM to the apical chamber in 100 μL PBS, while the

538 basolateral chamber contained 500 μL PBS. Diffusion from the apical to basolateral side was

539 measured by fluorescence reading in PBS on the basolateral side of the transwell system using

540 a SpectraMax M5 plate reader (Molecular Devices, San Jose, CA) at the ICCB-Longwood

541 Screening Facility. Fluorescence reading was normalized to the control.

542

543 **Caco-2 cell viability assay**. Caco-2 (undifferentiated in 96-well plates or day 21 to 25 of

544 differentiation in transwells) cell viability was measured using the MTT assay (Abcam, ab211091)

545 according to manufacturer's instructions. Cells were treated with compounds for 12-16 hours prior

546 to viability determination. Briefly, cell culture media was replaced with the MTT reagent and

547 incubated for 3 hours at 37ºC. Following incubation, the MTT reagent was replaced with the MTT

548 solvent and incubated for 15 min, followed by analysis in a SpectraMax M5 plate reader

549 (Molecular Devices, San Jose, CA) at the ICCB-Longwood Screening Facility at HMS.

550 Absorbance reading at 690 nm, as a measure of viability, was normalized to the control.

551

552 **Critical micelle concentration (CMC) assay**. CMC determination of groups of bile acids was

553 performed using a previously described assay using coumarin 6 as a fluorescent probe with minor

554 adaptations (Fluksman & Benny, 2019). Briefly, 6 mM coumarin 6 (Sigma) in dichloromethane

555 (Sigma) was added to Eppendorf tubes and allowed to evaporate for 30 min in a chemical hood.

556 400 µL of equimolar mixtures of bile acids at various concentrations to be tested were added to

557 tubes and rotated overnight at room temperature in the dark (unconjugated BAs: beta-muricholic

558 acid [βMCA], cholic acid [CA], deoxycholic acid [DCA], ursodeoxycholic acid [UDCA],

559 chenodeoxycholic acid [CDCA]); tauro-conjugated BAs: tauro-beta-muricholic acid [TβMCA],

560 tauro-cholic acid [TCA], tauro-deoxycholic acid [TDCA], tauro-ursodeoxycholic acid [TUDCA],

561 tauro-chenodeoxycholic acid [TCDCA]); glyco-conjugated BAs: glyco-cholic acid [GCA], glyco-

562 deoxycholic acid [GDCA], glyco-ursodeoxycholic acid [GUDCA], glyco-chenodeoxycholic acid

563 [GCDCA]). The next day, 200 µL of the solution was transferred to black 96 well plates (Costar),

564 and fluorescence intensity at 480/530 was measured using a SpectraMax M5 plate reader

565 (Molecular Devices, San Jose, CA) at the ICCB-Longwood Screening Facility. Fluorescence

566 intensity was plotted against the logarithm of the corresponding concentration and the CMC was

567 determined by the intersection of the two tangents created in the graph.

568

569 **Electron microscopy**. Caco-2 cells seeded on transwells were washed in PBS prior to fixation

570 in FGOP (Formaldehyde-Glutaraldehyde-Picric acid) fixative. Samples were fixed overnight in a

571 mixture of 1.25% formaldehyde, 2.5 % glutaraldehyde, and 0.03% picric acid in 0.1 M sodium

572 cacodylate buffer, pH 7.4. FGP fixative was diluted in PBS 1:1 before applying to the apical and

573 basolateral chamber of transwells. Fixed samples were stored at 4°C until further processing and

574 imaging by the Electron Microscopy Core at Harvard Medical School. All electron microscopy

575 imaging was performed by a blinded investigator.

576

577   For transmission electron microscopy, fixed tissues were washed with 0.1M sodium cacodylate

578   buffer and post fixed with 1% osmium tetroxide/1.5% potassium ferrocyanide (in H_2O) for 2 hours.

579   Samples were then washed in a maleate buffer and post fixed in 1% uranyl acetate in maleate

580   buffer for 1 hour. Tissues were then rinsed in ddH_2O and dehydrated through a series of ethanol

581   (50%, 70%, 95%, (2x)100%) for 15 minutes per solution. Dehydrated tissues were put in

582   propylene oxide for 5 minutes before they were infiltrated in epon mixed 1:1 with propylene oxide

583   overnight at 4C. Samples were polymerized in a 60ºC oven in epon resin for 48 hours. They were

584   then sectioned into 80nm thin sections and imaged on a JEOL 1200EX Transmission Electron

585   Microscope.

586

587   For negative staining for visualization of micelles, the sample was diluted in water and adsorbed

588   onto a glow-discharged carbon grid. Once the specimen was adsorbed on to the film surface, the

589   excess liquid was blotted off using a filter paper (Whatman #1) and the grid was floated on a small

590   drop (~5 µl) of staining solution (0.75% uranyl acetate). After 20 seconds the excess stain was

591   blotted off and the sample was air dried briefly before it was examined in the TEM.

592

593   **BSH activity assay.** BSH activity was quantified using a modified version of a previously

594   described method (Adhikari et al., 2020). Briefly, fresh cecal contents (approximately 20 mg) were

595   diluted in PBS to obtain a concentration of 1 mg/mL 100 µM glycochenodeoxycholic acid-d4

596   (GCDCA-d4) was added to the mixture and incubated at 37ºC for 30 minutes, then frozen in dry

597   ice for 5 minutes and stored at -80ºC until further analysis. On thawing, the mixture was diluted

598   with an equal volume of methanol and the slurry was centrifuged at 12,500 x g for 10 minutes.

599   The supernatant was removed into a clean Eppendorf tube and centrifuged again. The

600   supernatant was transferred to mass spectrometry vials and samples were analyzed as described

601   in Bile Acid Analysis in Supplementary Information.

602

603   **Statistical Analyses**. Data was quantified using software linked to indicated instruments and

604   plotted in GraphPad Prism 7. Statistical analyses were performed using GraphPad Prism and

605   Microsoft Excel software. Statistical significance was assessed using Student's or Welch's t tests,

606   one-way or two-way ANOVAs followed by multiple comparisons tests, and Mann-Whitney tests

607   wherever appropriate. **Figures 1E, F, 4G,** and **S16**: Intestines from all animals were stained, n=10

608   intestinal cell images per group were analyzed. For ZO-1 intensity, one-way ANOVA followed by

609   Tukey's multiple comparison test, for %ZO-1 membrane intensity and DAPI intensity, two-tailed

610   Welch's t test. Figures 2A, B: one-way ANOVA followed by Dunnett's multiple comparison test for

611   treatment vs. DMSO, one-way ANOVA followed by Tukey's multiple comparison test for

612   comparing treatments. **Figures 2D, E, 3D, E, G, 6E, F**: 2-way ANOVA followed by Sidak's multiple

613   comparisons test.

614

615   **Ethics.** Animals received humane care per criteria outlined in the Guide for the Care and Use of

616   Laboratory Animals by the National Academy of Sciences (National Institutes of Health publication

617   86-23, revised 1985) and in accordance with the Massachusetts General Hospital Institutional

618   Animal Care and Use Committee guidelines (Protocol 2007N000113).

619

620   **Author Contributions:** D.K.L., S.N.C., R.T.C, and A.S.D. conceived the project and designed

621   the experiments. D.K.L., M.S., Y.L, and S.C.B. performed all animal experiments,

622   immunofluorescence, staining, and transcriptional analyses on rat tissues. S.N.C. performed the

623   cell culture experiments, BA profiling, and preparation for electron microscopy. S.S. and L.Z.

624   performed pathology scoring of rat tissue. D.K.L., S.N.C., and A.S.D. wrote the manuscript. All

625   authors edited and contributed to the critical review of the manuscript.

626

640

641   **Competing Interests Statement:** The authors declare the following competing financial

642   interest(s): A.S.D. is an *ad hoc* consultant for Takeda Pharmaceuticals and Axial Therapeutics.

643   The other authors declare that no competing interests exist.

644

645   **Data Transparency Statement:** All data generated or analyzed during this study are included in

646   this article and its Supplementary Information.

840
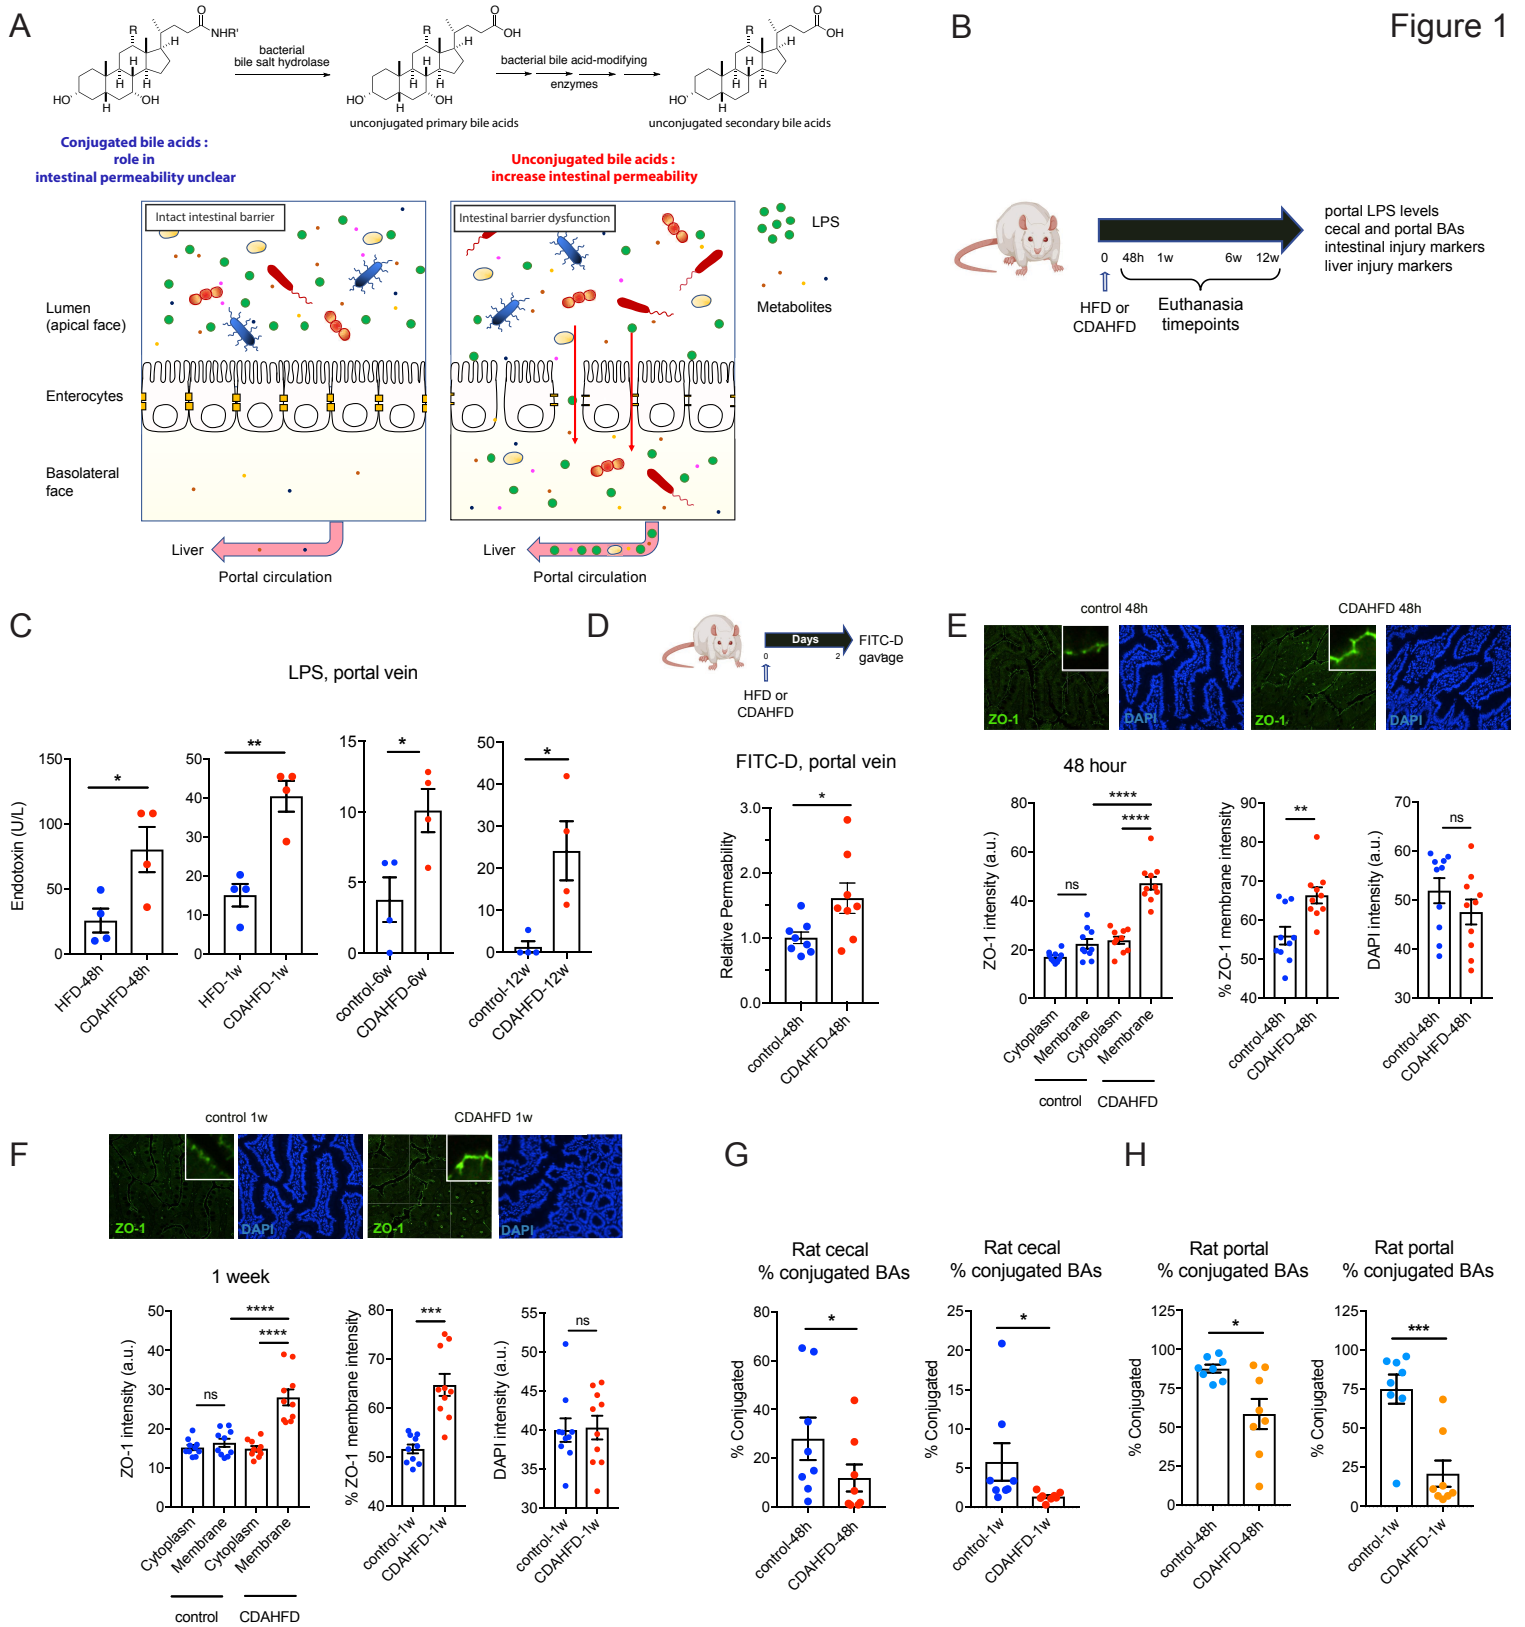

Figure 1

841

842 **Figure 1. CDAHFD-fed rats develop increased intestinal permeability at early timepoints**

843 **coinciding with decreased conjugated BA abundance.** (A) Human gut bacterial enzymes

844 transform conjugated primary BAs into unconjugated secondary BAs. While hydrophilic

845 unconjugated BAs damage epithelial integrity, the roles of unconjugated BAs and bacterial BSHs

846 in intestinal membrane integrity are unclear. (B) Schematic of rat intestinal permeability

847 timecourse experiment. A choline-deficient, L-amino acid defined, high-fat diet was fed to rats to

848 induce intestinal permeability and liver damage. High fat diet-fed rats served as controls. Rats

849 were euthanized at 48 hours, 1 week, 6 week, or 12 week timepoints. Tissues and blood were

850 collected for metabolite quantification and evaluation of intestinal and liver injury markers. (C)

851 Portal venous levels of lipopolysaccharide (LPS) were significantly increased in CDAHFD-fed rats

852 compared to control rats after 48h, 1w, 6w, and 12w on diet (n=4 per group, two-tailed Welch's t

853 test). (D) CDAHFD-fed rats developed increased intestinal permeability after 48h of diet.

854 Measurement of FITC-Dextran levels in systemic circulation after gavage in control and CDAHFD-

855 fed rats (n=8 per group, two-tailed Welch's t test). (E-F) CDAHFD induced increased expression

856 and apical membrane localization of ZO-1 at early timepoints. ZO-1 immunofluorescence staining

857 of ileum from control and CDAHFD-fed rats at 48h (E) and 1w (F) timepoints (n=10 intestinal cells

858 quantified per group, see Methods for statistical analyses). (G, H) Conjugated BA abundance was

859 reduced at early timepoints (48h, 1w) in the cecum (G) and portal vein (H) of CDAHFD-fed rats

860 as determined by UPLC-MS BA analysis from control and CDAHFD-fed animals (n=8 per group,

861 two-tailed Welch's t test, see Supplementary Information for concentrations of total and individual
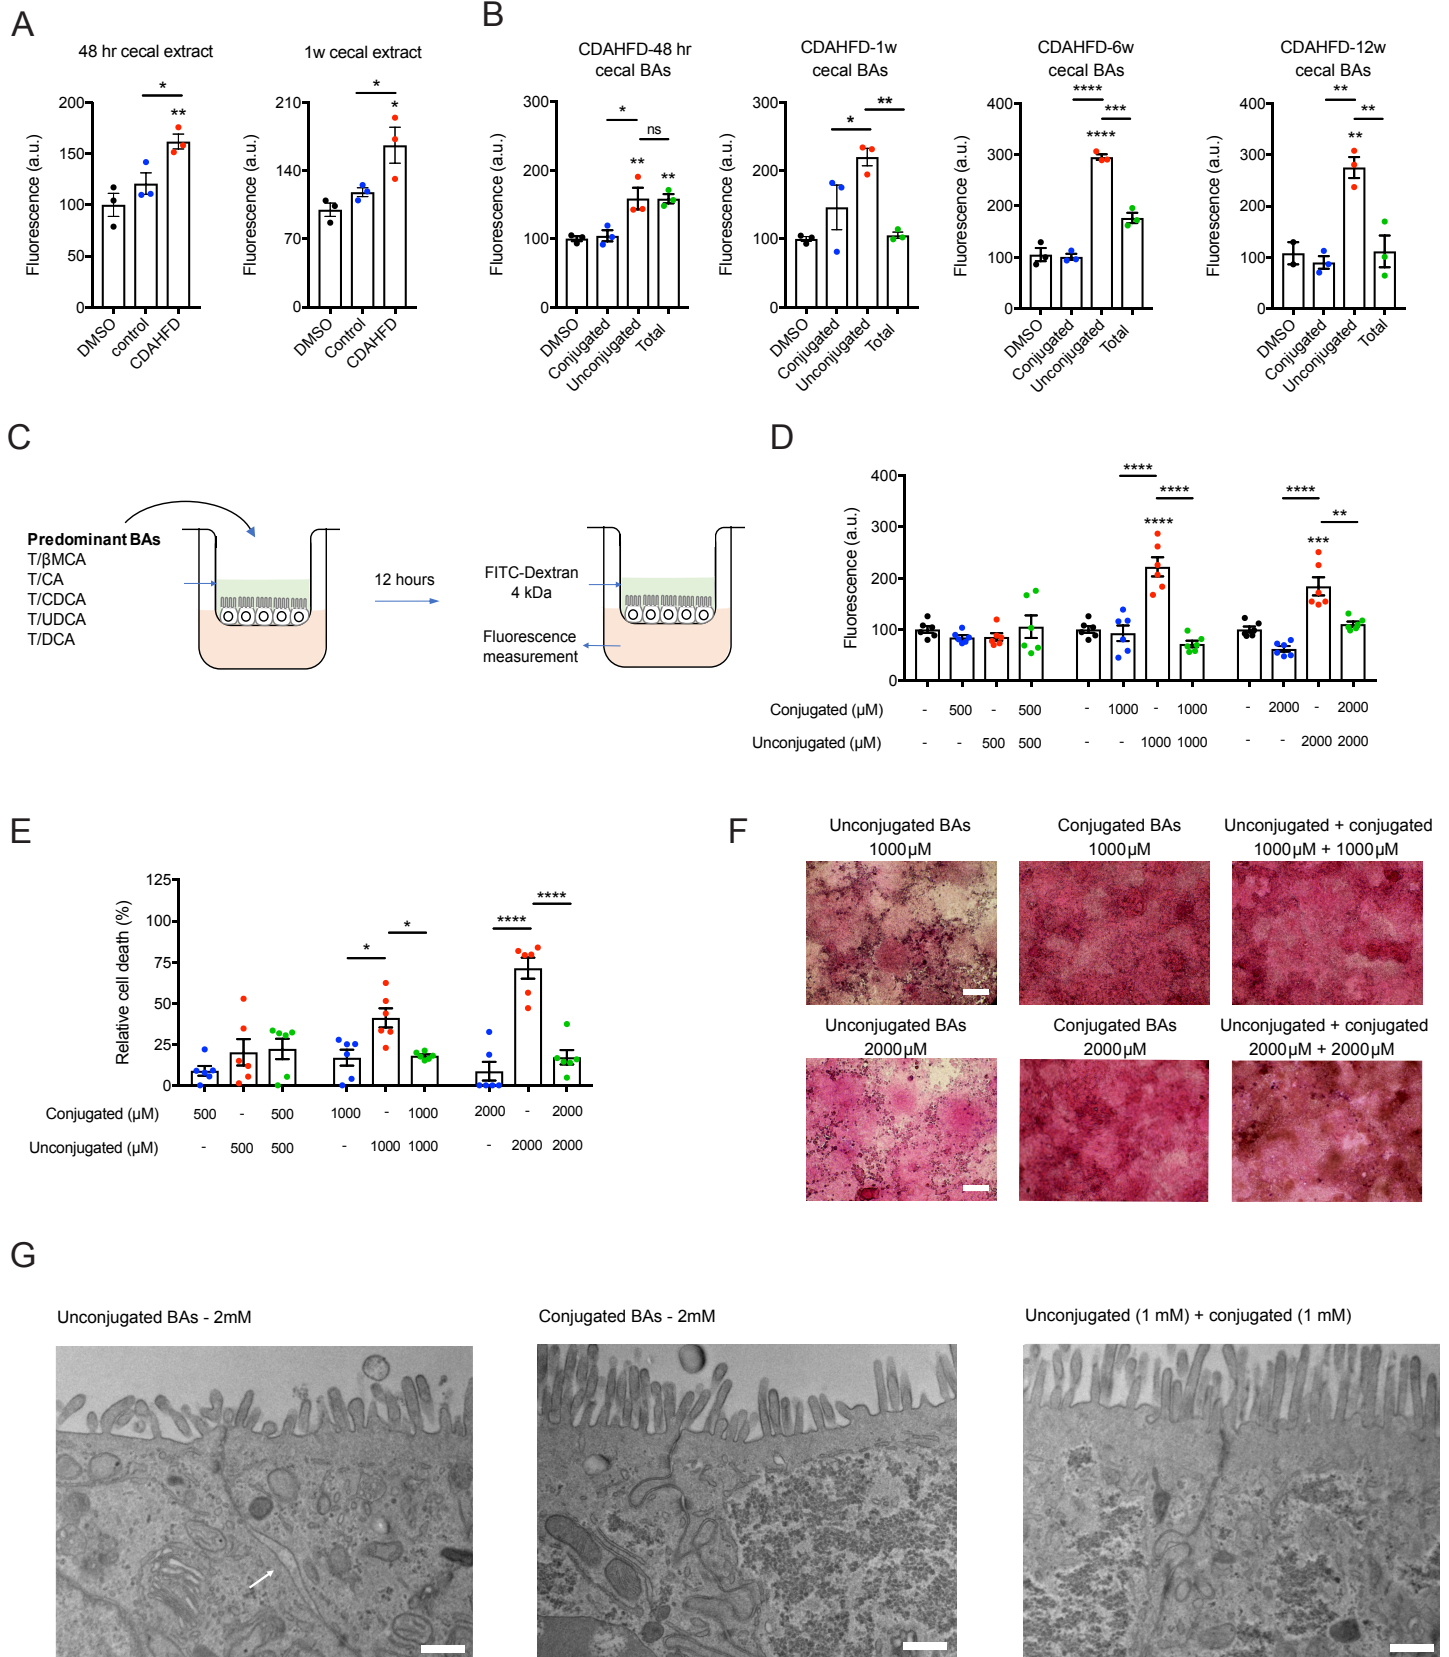

862 BAs in cecal contents and portal vein at 48h, 1w).

863 See Methods for statistical analyses. *$p<0.05$, **$p<0.005$, ***$p<0.001$, ****$p<0.0001$. Bars

864 represent mean ± SEM.

865

Figure 2

866

867 **Figure 2. Conjugated BAs protect epithelial monolayers from unconjugated BA-induced**

868 **permeability.**

869 (A) Cecal extracts from CDAHFD-fed rats at early timepoints caused increased epithelial

870 permeability. Caco-2 monolayer permeability after exposure to purified cecal extracts from control

871 and CDAHFD-fed rats at indicated timepoints as measured by FITC-Dextran passage into the

872 basolateral chamber over 12 hours (n=3 per group, see Methods for statistical analyses). (B)

873 Conjugated BAs alone did not increase Caco-2 monolayer permeability at concentrations found

874 in the cecum of CDAHFD rats, and when combined with unconjugated BAs, conjugated BAs

875 protected against unconjugated BA-induced permeability (n=3 per group, see Methods for

876 statistical analyses). (C) Schematic of in vitro permeability experiment. Conjugated BAs

877 (equimolar concentrations of TβMCA, TCA, TCDCA, TUDCA, TDCA), unconjugated BAs

878 (equimolar concentrations of βMCA, CA, CDCA, UDCA, DCA), and combined BA pools

879 (equimolar concentrations of both pools) were added to the apical chamber of a transwell system

880 containing a Caco-2 monolayer and incubated for 12 hours before addition of FITC-Dextran 4kDa

881 and fluorescence measurement from basolateral chamber. (D) Conjugated BAs protected against

882 unconjugated BA-induced Caco-2 monolayer permeability at physiologic concentrations (n=6 per

883 group, see Methods for statistical analyses). (E) Conjugated BAs protected epithelial monolayers

884 from unconjugated BA-induced cell death. Cell viability of Caco-2 cells measured by MTT assay

885 (n=6 per group, see Methods for statistical analyses). (F) Conjugated BAs protected the physical

886 integrity of epithelial monolayers from unconjugated BA-induced damage. Representative light

887 microscopy images of H&E-stained Caco-2 monolayers after exposure to BA pools. Scale bar=20

888 μm. (G) Conjugated BAs prevented the development of unconjugated BA-induced tight junction

889 dilatation. Representative TEM images of Caco-2 cells from transwells after exposure to BA pools

890 at indicated concentrations. The white arrow points to tight junction dilatation. Scale bar=500 nm.

891   see Supplementary Information for additional representative TEM images. Unless otherwise

892   specified, all experiments were performed in triplicate. See Methods for statistical analyses. Data

893   not marked with asterisk(s) are not significant. *$p<0.05$, **$p<0.005$, ***$p<0.001$, ****$p<0.0001$.

Figure 3

896
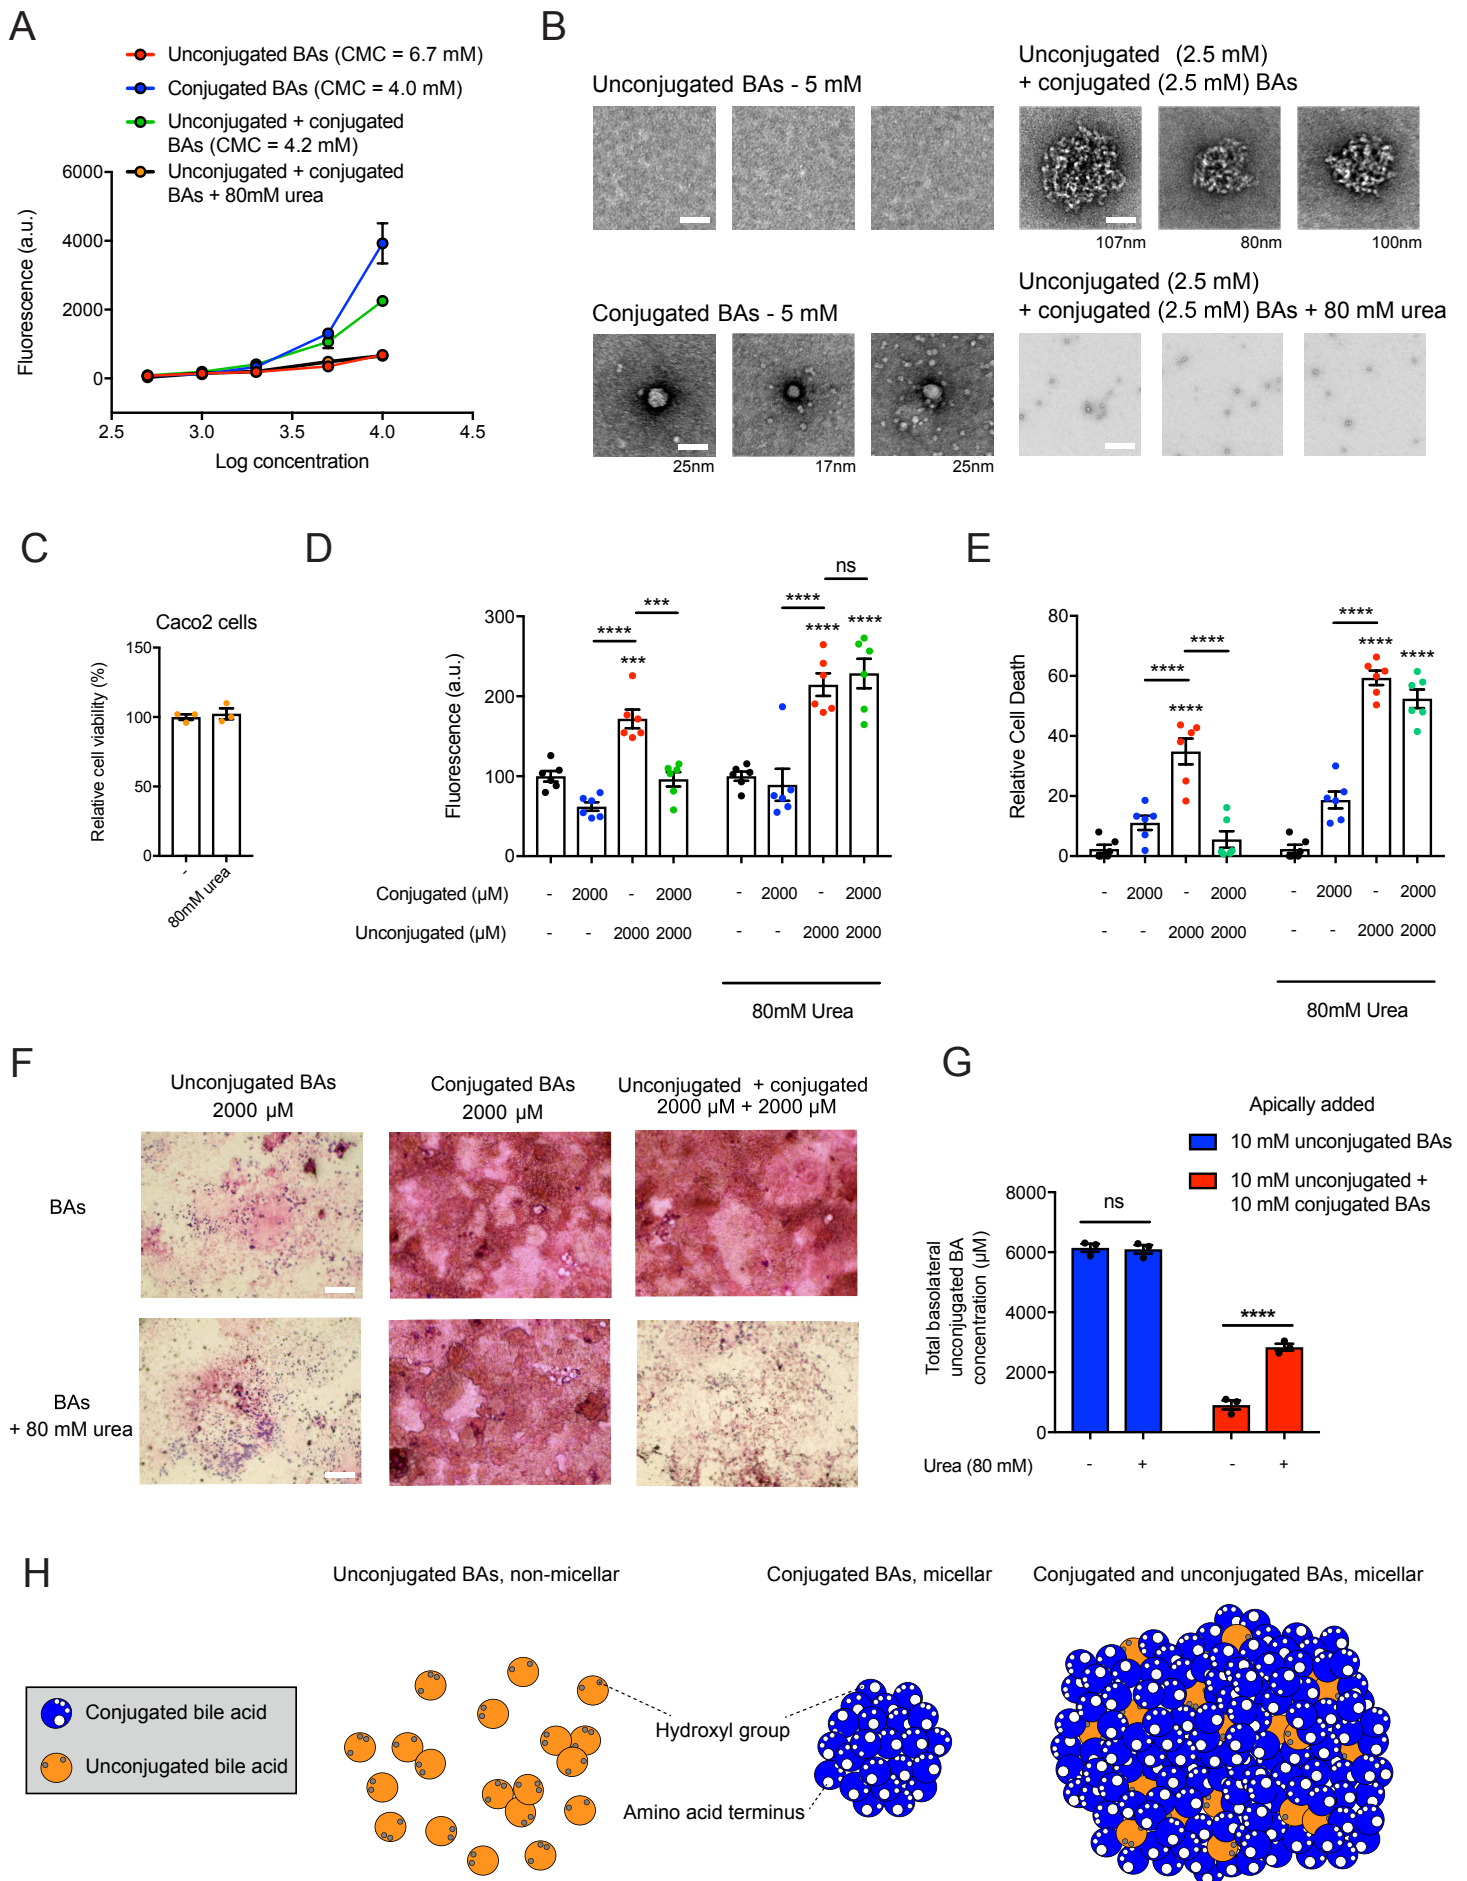

Figure 3. Conjugated and unconjugated BAs form micelles that sequester unconjugated BAs and prevent epithelial damage.

(A) Conjugated BAs alone (equimolar concentrations of TβMCA, TCA, TCDCA, TUDCA, TDCA) and conjugated BAs combined with unconjugated BAs (equimolar concentrations of conjugated BAs with βMCA, CA, CDCA, UDCA, DCA) exhibited lower CMCs than unconjugated BAs alone. Micelle formation was disrupted after addition of urea (80 mM) (n=3 per group). (B) EM images of micelles formed from BA pools at indicated concentrations. While detectable micelles were visible in the conjugated BAs alone or unconjugated plus conjugated BA pools, no detectable micelles were visible in the unconjugated BAs or unconjugated plus conjugated BAs plus urea (80 mM) pools. Scale bar=50 nm, diameter of micelle indicated beneath each image (n=3 images per group). (C) MTT cell viability assay of Caco-2 cells in the presence or absence of 80 mM urea indicated that urea did not impact Caco-2 cell viability (n=3 per group, not significant by two-tailed Welch's t test). (D) Micelle formation was necessary for the protective effect of conjugated BAs on epithelial permeability. Permeability measured by fluorescence (FITC-Dextran) in basolateral chamber in the presence or absence of 80 mM urea (n=6 per group, see Methods for statistical analyses). (E) Micelle formation was necessary for the protective effect of conjugated BAs on cell viability. Caco-2 cell viability measured by MTT assay in the presence or absence of urea (n=6 per group, see Methods for statistical analyses). (F) Micelle formation was necessary for the protective effect of conjugated BAs on epithelial layer integrity. Representative light microscopy images of H&E-stained Caco-2 monolayers in transwells in the presence or absence of urea. (G) Addition of urea to a mixed BA pool led to increased unconjugated BA passage across a Caco-2 monolayer. Quantification of basolateral concentrations of unconjugated BAs by UPLC-MS (n=3 per group, see Methods for statistical analyses). (H) Model for the sequestration of unconjugated BAs in micelles by conjugated BAs. BAs shown in cross-section and micellar shape depictions

41

921   based on previous micelle models (Carey & Small, 1972; Faramarzi et al., 2017). While

922   unconjugated BAs are largely non-micellar in solution, both conjugated BAs and mixtures of

923   unconjugated and conjugated BAs form micelles. Unless otherwise specified, all experiments

924   were performed in triplicate. See Methods for statistical analyses. Data not marked with

925   asterisk(s) are not significant. $*p<0.05$, $**p<0.005$, $***p<0.001$, $****p<0.0001$. Bars represent

926   mean ± SEM.

928

929 **Figure 4. BSH inhibition increases intestinal conjugated BAs and prevents intestinal**

930 **barrier dysfunction in CDAHFD-fed rats.** (A) Schematic for the inhibition of bacterial BSH

931 activity by the covalent pan-BSH inhibitor AAA-10 (Adhikari et al., 2021; Adhikari et al., 2020). (B)

932 Schematic of rat intestinal permeability prevention experiment. Fats were fed CDAHFD and

933 administered either AAA-10 (10 mg/kg/dose) or vehicle twice daily by gavage. Rats were

934 euthanized at 48 hours or 1 week. Tissues and blood were collected for metabolite quantification

935 and evaluation of intestinal injury markers (n=8 per for all timepoints). (C) UPLC-MS analysis of

936 cecal contents of vehicle- and AAA-10-treated animals. Cecal AAA-10 levels were within the

937 concentration range previously shown to be effective for inhibiting BSH activity (Adhikari et al.,

938 2021; Adhikari et al., 2020). (D) Cecal BSH activity was reduced after 1 week of AAA-10

939 treatment. BSH activity was determined by quantifying conversion of GCDCA-d4 to CDCA-d4 in

940 feces from vehicle- or AAA-10-treated animals (two-tailed Welch's t-test). (E) Cecal conjugated

941 BA abundance was significantly increased in AAA-10-treated rats after 1 week (two-tailed Welch's

942 t test, see Supplementary Information for concentrations of total and individual BAs in cecal

943 contents at 1w). (F) Portal venous LPS levels were reduced in AAA-10 treated rats after 48h and

944 1w of AAA-10 treatment (two-tailed Welch's t test). (G) AAA-10 treatment prevented aberrant ZO-
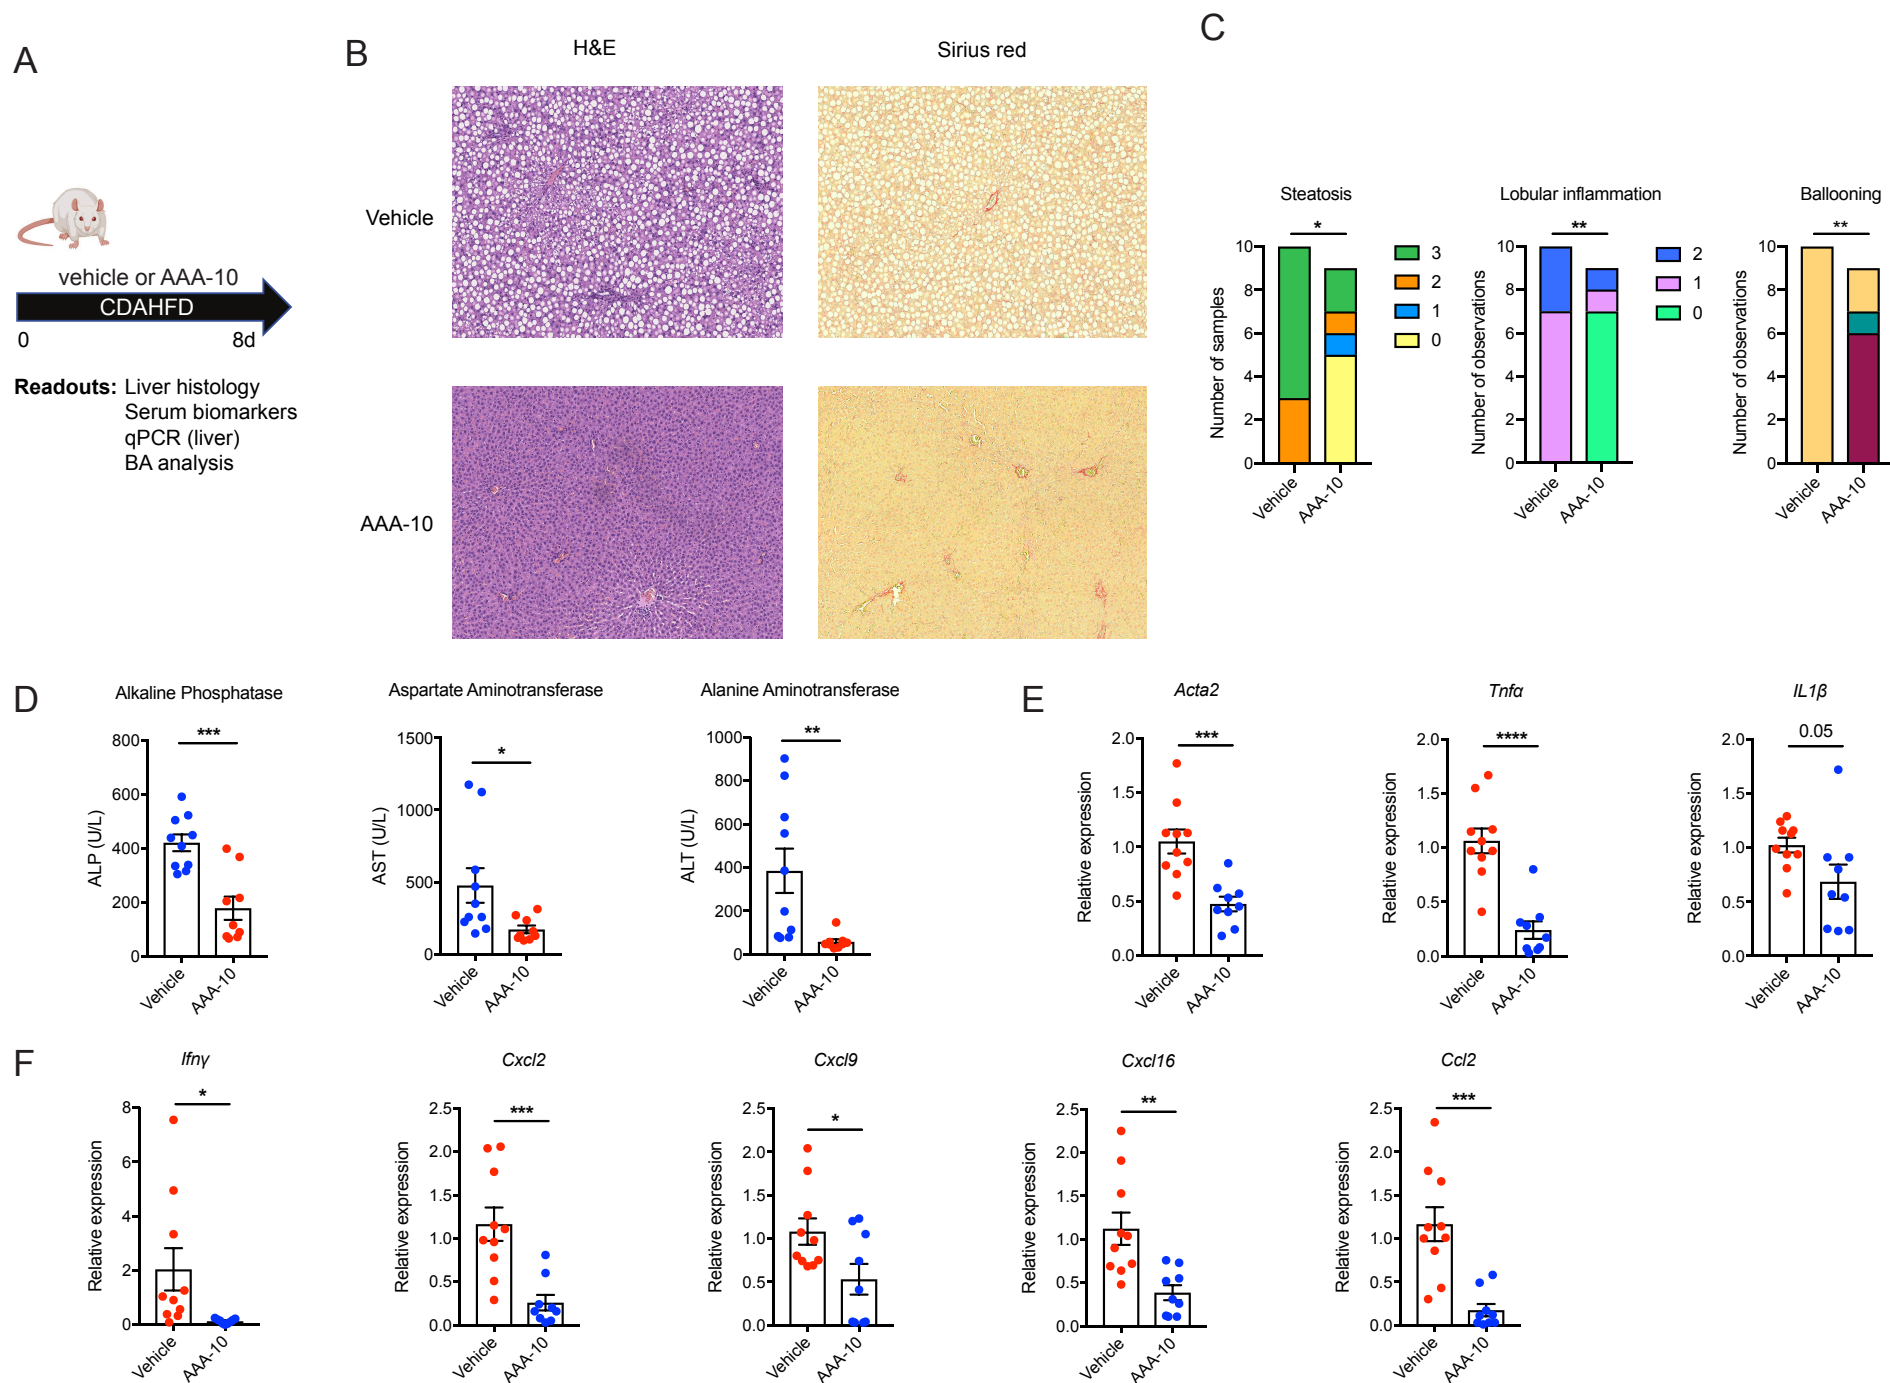

945 1 subcellular localization. ZO-1 immunofluorescence and DAPI counterstaining of rat ileum from

946 vehicle and AAA-10 treated CDAHFD-fed rats at 48h and 1w (n=10 intestinal cells quantified per

947 group, see Methods for statistical analyses). Data not marked with asterisk(s) are not significant.

Figure 5

950

951 **Figure 5. BSH inhibition prevents hepatic inflammation in CDAHFD-fed rats.**

952 (A) Schematic of rat liver damage prevention experiment. Rats were fed CDAHFD and

953 administered either AAA-10 (10 mg/kg/dose) or vehicle twice daily by gavage. Rats were

954 euthanized after 8 days. Tissues and blood were collected for metabolite quantification and

955 evaluation of liver injury markers (n=10 in vehicle group, n=9 in AAA-10 group for all timepoints).

956 (B) AAA-10 treatment prevented development of hepatic steatosis and inflammation in CDAHFD-

957 fed rats. Representative H&E staining of liver tissue is shown. (C) AAA-10 treatment prevented

958 development of hepatic inflammation. Histologic scoring of steatosis, hepatocyte ballooning, and

959 lobular inflammation in vehicle- and AAA-10-treated animals. Mann-Whitney test. (D) Serum ALT,

960 AST, and ALP levels were decreased in AAA-10-treated compared to vehicle-treated rats, two-

961 tailed Welch's t test. (E, F) AAA-10 treatment attenuated hepatic gene expression of pro-

962 inflammatory and pro-fibrotic genes in CDAHFD-fed rats as determined by RT-qPCR analysis of

963 indicated genes. Two-tailed Welch's t test. *$p<0.05$, **$p<0.005$, ***$p<0.0005$, ****$p<0.0001$. Bars

964 represent mean ± SEM.

965

Figure 6
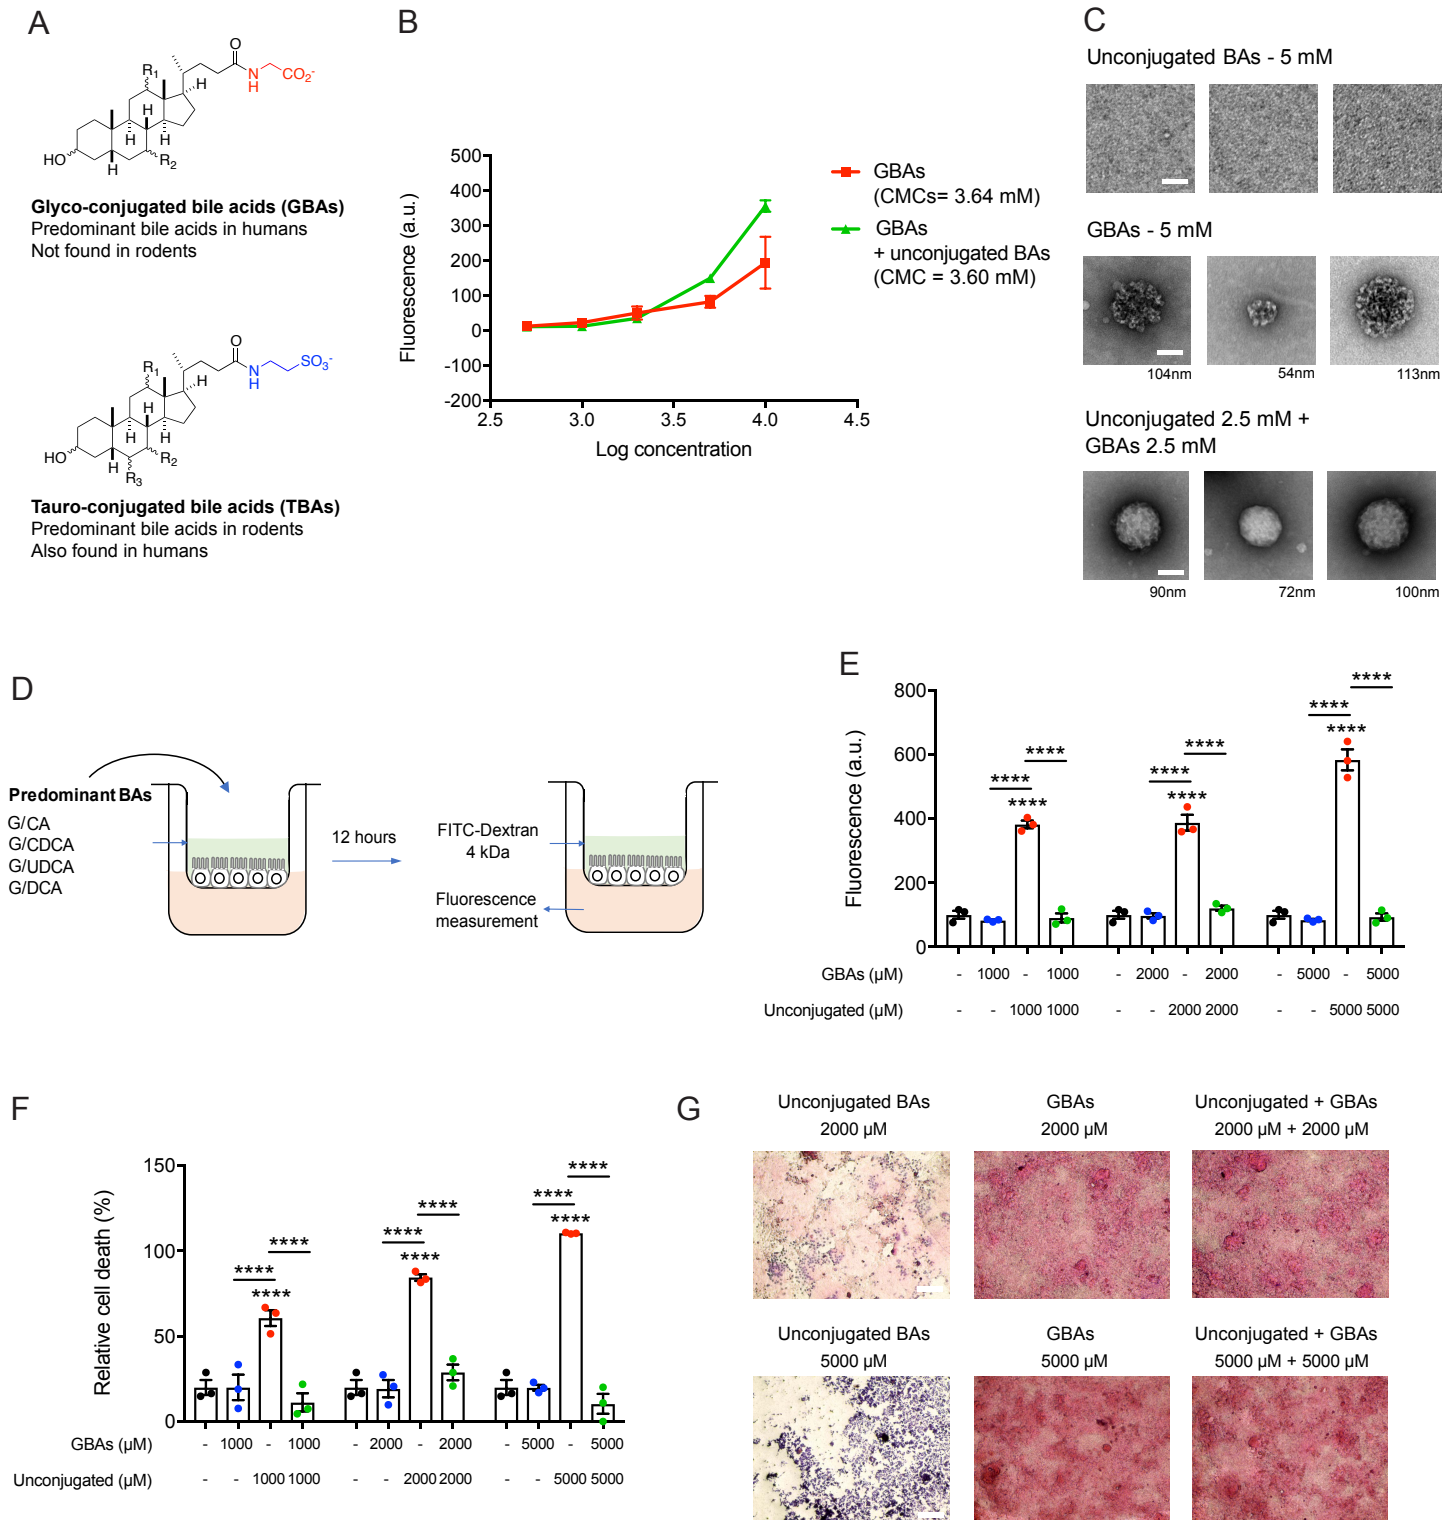

966

967 **Figure 6. Predominant human glyco-conjugated BAs sequester unconjugated BAs in**

968 **micelles and prevent epithelial damage in vitro.** (A) Structures of glyco- and tauro-conjugated

969 BAs (GBAs and TBAs, respectively). While TBAs are found in both rodents and humans, GBAs

970 are the predominant conjugated BAs in humans and are not present in rodents. (B) Pools of GBAs

971 alone (equimolar concentrations of GCA, GCDCA, GUDCA, GDCA) and GBAs plus unconjugated

972 BAs (equimolar concentrations of glyco-conjugated BAs with βMCA, CA, CDCA, UDCA, DCA)

973 exhibited CMCs of 3.64 mM and 3.60 mM, respectively, indicating efficient micelle formation (n=3

974 per group). (C) EM images of micelles formed from BA pools at indicated concentrations. Similar

975 to TBAs (see Figure 3), while detectable micelles were visible in the GBAs alone or unconjugated

976 BAs plus GBA pools, no detectable micelles were visible in the unconjugated BAs pool. Scale

977 bar=50 nm, diameter of micelle indicated beneath each image. (D) Schematic of in vitro

978 permeability experiment. Equimolar concentrations of GBAs, unconjugated BAs, and combined

979 BA pools were added to the apical chamber of transwell system containing Caco-2 monolayer

980 and incubated for 12 hours before addition of FITC-Dextran 4kDa and fluorescence measurement

981 from basolateral chamber. (E) GBAs protected against unconjugated BA-induced Caco-2

982 monolayer permeability at physiologic concentrations (n=3 per group, see Methods for statistical

983 analyses). (F) GBAs protected epithelial monolayers from unconjugated BA-induced cell death.

984 Cell viability of Caco-2 cells measured by MTT assay (n=3 per group, see Methods for statistical

985 analyses). (G) GBAs protected the physical integrity of epithelial monolayers from unconjugated

986 BA-induced damage. Representative light microscopy images of H&E-stained Caco-2

987 monolayers after exposure to BA pools. Scale bar=20 μm. Unless otherwise specified, all

988 experiments were performed in triplicate. See Methods for statistical analyses. Data not marked

989 with asterisk(s) are not significant ****p<0.0001. Bars represent mean ± SEM.
