ABSTRACT

It is estimated that nearly 50% of mammalian transcripts contain at least one upstream open reading frame (uORF), which are typically one to two orders of magnitude smaller than the downstream main ORF. Most uORFs are thought to be inhibitory as they sequester the scanning ribosome, but in some cases allow for translation re-initiation. However, termination in the 5' UTR at the end of uORFs resembles pre-mature termination that is normally sensed by the nonsense-mediated mRNA decay (NMD) pathway. Translation re-initiation has been proposed as a method for mRNAs to prevent NMD. Here we test how uORF length influences translation re-initiation and mRNA stability. Using custom 5' UTRs and uORF sequences, we show that re-initiation can occur on heterologous mRNA sequences, favors small uORFs, and is supported when initiation occurs with more initiation factors. After determining reporter mRNA half-lives and mining available mRNA half-life datasets for cumulative uORF length, we conclude that translation re-initiation after uORFs is not a robust method for mRNAs to evade NMD. Together, these data support a model where uORFs have evolved to balance coding capacity, translational control, and mRNA stability.

RUNNING TITLE: Translational control by uORF length

KEYWORDS: eIF; mRNA decay; non-canonical initiation; ribosome; translational control

INTRODUCTION

Canonical eukaryotic translation initiation follows a cap- and scanning-dependent mode^{1,2}. First, the 5' m⁷G cap recruits the eIF4F complex via the eIF4E cap-binding protein. eIF4F also provides an opportunity for the mRNA to form a close-loop conformation with the poly(A) tail and PABP that is thought to increase translation efficiency. eIF4F then recruits the 43S pre-initiation complex (PIC), which is comprised of the 40S small ribosomal subunit, eIF1, eIF1A, eIF3, eIF5, and the ternary complex (eIF2•GTP•Met-tRNA^{Met}). The 43S PIC then scans 5' to 3' in search of an AUG start codon. The 48S initiation complex is formed after start codon recognition and eIF2 subsequently hydrolyzes GTP to release Met-tRNA^{Met}. After initiation factors dissociate, initiation is completed once the 60S large ribosomal subunit joins with aid from eIF5B•GTP to form the complete 80S ribosome.

Due to the 5' to 3' nature of the scanning 43S PIC, the first AUG start codon in the mRNA is often recognized most efficiently and is primarily used for protein synthesis—albeit the surrounding context (i.e., Kozak sequence) and distance from the 5' end influences start codon recognition. A major hurdle for the ribosome from recognizing the AUG start codon of the protein encoding main open reading frame (ORF) is the presence of upstream start codons and upstream open reading frames (uORFs) in the 5' untranslated region (UTR). Nearly 50% of mammalian 5' UTRs harbor at least one uORF³. Some uORFs do not present much of an obstacle as recent work has shown that the footprint of the eIF4F complex creates a “blind spot” in the first ~50 nucleotides (nts) for the ribosome and only AUG start codons after this point are efficiently recognized⁴. However, 5' UTRs are often larger than the length of this blind spot and contain multiple uORFs. In fact, stress response mRNAs contain multiple evolutionary conserved uORFs that are thought to be key regulators of translation^{5,6}. For example, the *ATF4* mRNA 5' UTR contains at least two uORFs. It has been proposed for *ATF4* mRNA that most scanning PICs initiate at the start codon of uORF1 and that translation of uORF1 stimulates or

favors translation re-initiation at uORF2 under normal physiological conditions. Re-initiation occurs when a ribosome terminates and releases the polypeptide but fails to have the small 40S subunit recycled off and subsequently continues to scan downstream in search of a start codon^{5,7}. Since uORF2 overlaps the ATF4 coding sequence and ends downstream from the beginning of the ATF4 coding sequence, ATF4 protein is not efficiently synthesized unless uORF2 is skipped during cell stress⁵⁻⁷.

It has been proposed that re-initiation could negate the ribosome from triggering nonsense mediated mRNA decay (NMD) during termination at uORFs in the 5' UTR or at premature termination codons within the major ORF since the late steps of termination and/or ribosome recycling are not completed⁸⁻¹⁵. In mammalian cells, NMD is triggered by termination ≥ 50 nts upstream of an exon-junction complex (EJC) or upstream of long 3' UTRs^{16,17}. Ribosomes that re-initiate would also displace EJCs and mRNA-bound Upf1 further preventing NMD during subsequent rounds of translation¹⁵. In this report, we test how uORF length affects translation re-initiation and mRNA stability. Our data show that uORF length robustly controls re-initiation but higher re-initiation efficiency does not protect mRNAs from NMD. Reporter mRNAs with small or large uORFs had orders of magnitude difference in allowing re-initiation but had remarkably similarly shortened half-lives. Transcriptome-wide analysis of cumulative uORF length and mRNA half-life also suggests whether an uORF is translated, not its length or re-initiation efficiency, is the primary influence if termination in the 5' UTR stimulates mRNA decay.

RESULTS AND DISCUSSION

To specifically measure re-initiation and how it impacts mRNA stability, we designed nanoLuciferase (nLuc) reporters to harbor an uORF that maximally prevents leaky scanning of

the PIC and avoids reporter signal from ribosome readthrough. This was achieved by using a synthetic 5' UTR with three important elements: i) a 72 nt CAA-repeat leader sequence to allow for an unstructured sequence that is in the optimal length window for cap- and scanning-dependent initiation ⁴, ii) an uORF comprised of three AUG start codons in perfect Kozak context (3XAUG), iii) and a 16 nt unstructured CAA-repeat linker between the uORF and nLuc start codon to separate and frameshift the ORFs (**Fig. 1A**).

We next used ribosome toeprinting to confirm that the 3XAUG start codon uORF prevents leaky scanning and sequesters all detectable scanning PICs from the nLuc ORF (**Fig. 1B, C**). *In vitro* translation extracts were pre-incubated with lactimidomycin (binds to the E site of the 60S subunit) to robustly inhibit the first translocation cycle of the 80S ribosome after initiation ¹⁸. The 20 nt FAM-labeled reverse primer targeted a region in the nLuc coding sequence that was downstream enough to detect toeprints of 80S ribosomes at the AUG start codon of nLuc (175 nt), which would be present if leaky scanning past the uORF occurred, and the uORF (218 nt). Indeed, for the uORF reporter mRNA, toeprint signal mapped primarily to the first and second AUG start codon of the uORF (218 and 210 nt, respectively), with some detectable signal mapping to the third uORF start codon (**Fig. 1C**). Signal from unused primer is seen at 20 nt. Importantly, no signal was mapped to the start codon of nLuc (175 nt) which is in alignment with the design for the uORF to trap all scanning PICs.

As an additional control, we mutated the AUG start codons of the uORF to AAA (which does not support initiation) to allow all scanning PICs to bypass the uORF and initiate at the AUG start codon of nLuc (**Fig. 1A**). As expected, ribosome toeprints of this mutant uORF reporter produced signal that only mapped to the AUG start codon of nLuc (**Fig. 1D**). Similar results were seen with the uORF consisting of 10 consecutive AUG codons, but because the start codons were not in optimal context more initiation within the uORF was observed

(Supplemental Fig. S1). Together, these data support that the designed uORF can robustly capture all detectable scanning PICs and allows all luciferase signal to be generated from re-initiation.

Consistent with uORFs generally being translational repressive elements, the small uORF repressed translation of nLuc 5-10-fold *in vitro* and in HeLa cells (**Fig. 2A, B**). Translation of nLuc was rescued when the AUG start codons in the uORF were mutated to AAA codons. Given that the average uORF in mammalian transcripts are much smaller than the main annotated protein coding ORFs (16 codons vs 460 codons)³, we tested how expanding the uORF length would affect re-initiation. The uORF was expanded from 9 codons to 561 codons by inserting the HaloTag-GFP (HT-GFP) coding sequence immediately downstream from the 3XAUG start codons and upstream of the stop codon. In both *in vitro* and in HeLa cells, the large uORF repressed translation of nLuc orders of magnitude more than the small uORF (**Fig. 2A, B**). To confirm this observation was not due to differences in the sequence that the ribosome occupies during initiation and termination in the large uORF, we made a truncated HT-GFP uORF (total of 24 codons) that preserved the first and last 24 nt of the HT-GFP coding sequence (**Fig. 1A**). The truncated uORF rescued expression compared to the larger uORF *in vitro* and in HeLa cells (**Fig. 2A, B**). However, because the truncated uORF is still ~3X larger than the small uORF, it was more repressive than the small uORF.

It remains possible that the greater repression of the large uORF could be due to the HT-GFP coding sequence forming an unexpected secondary structure that inhibited the ribosome or sequestered the 5' cap. This seems unlikely because we obtained equivalent results with a different but equally large uORF sequence (**Supplemental Fig. S2 and Supplemental Fig. S3**). Additionally, the sequence that could influence an initiating ribosome based off the known ribosome footprint size was preserved between the large and truncated

uORFs. Nevertheless, we further tested this by fusing the 3XAUG start codon to a P2A “ribosome skipping motif” and the nLuc ORF (**Fig. 2C**). The P2A motif allows the ribosome to release the nascent polypeptide but continue elongation^{19,20}. Thus, in this test, the same nLuc polypeptide from both reporters is being synthesized and assayed. Consistent with the HT-GFP-P2A reporter sequence being 3.5X larger than the control (776 codons vs 224 codons), the larger HT-GFP-P2A reporter was translated ~4X less (**Fig. 2D**). When the nLuc signal was normalized for ORF length, the difference between the two sized reporters was only ~10% (**Fig. 2D**). This small difference suggests that ribosomes initiate at the small and large uORFs almost equally and does not rationally explain the 100-1000-fold difference seen in the re-initiation reporters (**Fig. 2A, B**). Together, these data support that large uORFs are more repressive than small uORFs because they allow less translation re-initiation.

Recent reports using crosslinking and immunocapture of initiation factors (eIFs) have provided evidence that some eIFs may linger on the ribosome after initiation and could aid re-initiation if present after termination of a small uORF^{21,22}. With this in mind, we next tested if re-initiation after small uORFs is as efficient if they are translated by ribosomes requiring less eIFs during initiation. We achieved this by taking advantage of class I-IV cap-independent viral internal ribosome entry sites (IRES) that require subsets of eIFs²³ (**Fig. 3A, B**). In certain cases, IRES can stimulate initiation without requiring any eIFs or the initiator tRNA (**Fig. 3A, B**). It was apparent that IRES-mediated translation is less efficient than canonical translation and we were only able to test the effect of the small uORF and still have luciferase signal above background in the linear range. In alignment with the model that eIFs that are stubbornly bound to the ribosome aid in re-initiation^{21,22}, we observed that the uORFs repressed translation greater when the IRES utilized less initiation factors (**Fig. 3B,C**). For example, the uORF translated by the Cricket Paralysis Virus Intergenic Region (CrPV IGR) IRES, which does not require any eIFs or the initiator tRNA^{24,25}, repressed translation the most (**Fig. 3C**).

The presence of uORFs presents a major challenge to mRNAs as termination in the 5' UTR resembles how ribosomes recognize deleterious premature termination codons (PTCs) through nonsense-mediated mRNA decay (NMD). Termination ≥ 50 nts upstream of an exon junction complex (EJC) typically robustly triggers NMD in mammalian cells^{16,17}. However, termination at uORFs almost certainly occurs upstream of an EJC if the uORF is translated during the pioneering round of translation. Others have postulated that re-initiation could be a method that ribosomes use to bypass triggering NMD at PTCs within the major ORF⁸⁻¹⁵. We next asked if large uORFs, which do not favor re-initiation (**Fig. 2**, **Supplemental Fig. S2**, **Supplemental Fig. S3**), stimulate mRNA decay more than small uORFs in cells. Using a Tet-Off system to selectively and robustly turn off reporter transcription, we measured reporter mRNA levels over an 8 hr time course after the addition of doxycycline. In this experiment, we used the same reporter design as described in **Fig. 1** with the addition of a small functional intron in nLuc ORF. As a positive control, we included a reporter that harbors an intron in the 3' UTR which should stimulate NMD and have a shorter mRNA half-life. As expected, the no uORF + 3' UTR intron reporter had a ~2hr shorter half-life than the control no uORF reporter (3.71 ± 0.52 hr vs. 5.84 ± 1.12 hr, respectively) (**Fig. 4B**). The small and large uORF reporters had even shorter mRNA half-lives of 3.16 ± 0.34 hr and 2.49 ± 0.33 hr, respectively, (**Fig. 4C, D**). Although we see 100-fold difference in re-initiation between the small and large uORF in cells (**Fig. 2B**), the half-life of the large uORF reporter was only ~40 min shorter than the small uORF reporter (**Fig. 4C, D**). We further investigated the connection between uORF length and mRNA stability on a transcriptome-wide scale by mining published BRIC-seq datasets^{26,27} and determined the cumulative uORF length for each mRNA. We found no statical difference between the mean mRNA half-life of transcripts that contained varying cumulative uORF lengths in multiple data sets (**Fig. 4E** and **Supplemental Fig. S4**). However, transcripts without an uORF were on average more stable and had longer half-lives (**Fig. 4E** and **Supplemental Fig.**

S4A). Collectively, these data suggest translation re-initiation after uORFs is not a robust method for mRNAs to evade NMD.

Together, our data support a model where uORF length controls re-initiation but not termination-dependent decay. Whether an uORF is translated, not its length or re-initiation efficiency, is the primary influence if termination in the 5' UTR stimulates mRNA decay. The coding capacity of a single mRNA can be increased with larger uORFs, but a trade-off ensues as they do not favor re-initiation and provide less translational regulation (**Supplemental Fig. S4B**). This control can be regulated by leaky scanning, by complete bypass of the uORF if the scanning 40S ribosome lacks a ternary complex (TC), or if the uORF harbors a start codon in sub-optimal Kozak context. For example, many stress response mRNAs harbor uORFs that are not translated during stress conditions ^{5,6}. During cell stress, phosphorylation of eIF2 α at Ser51 inhibits translation but does not block 40S ribosomes lacking a TC from being loaded and scanning. Current models suggest that TCs can then rejoin the scanning 40S ribosome downstream of the uORFs but upstream of the main ORF. Consistent with these models and uORFs being skipped prevents NMD, stress response mRNAs are often elevated during cell stress ^{28,29}. Clearly, mammalian evolution has not favored large uORFs as the average mammalian uORF is 16 codons ³. This may be partially explained not only by the fact that large uORFs provide higher chances of ribosome collisions and non-optimal codons that also stimulate mRNA decay ³⁰⁻³³, but they also prevent translation of the downstream main ORF by decreased re-initiation.

MATERIALS AND METHODS

Plasmids

Complete sequences of reporter plasmid inserts are located in the Supplementary Material. All plasmids were derived from previously described pcDNA3.1(+)/AUG-nLuc-3XFLAG and pcDNA3.1-D/CrPV IGR IRES nLuc-3XFLAG³⁴. The CrPV IGR IRES reporter was additionally modified to contain a strong hairpin upstream of IRES element to block scanning pre-initiation complexes. The HT-GFP ORF was taken from pHaloTag-EGFP (a gift from Thomas Leonard and Ivan Yudushkin; Addgene plasmid # 86629)³⁵. pGL4.13 (encodes Firefly Luciferase [FFLuc]) was obtained from Promega (# E6681). IRES-containing nLuc reporters were generated using an overlapping PCR method and cloned into pcDNA3.1(+) or pcDNA3-1D. The PV IRES template was pcDNA3 RLUC POLIRES FLUC and was a gift from Nahum Sonenberg (Addgene plasmid # 45642)³⁶. The EMCV IRES and HCV IRES templates were kind gifts from Aaron Goldstrohm. 5' UTRs, uORFs, introns, and mutations were introduced using the Q5 Site-Directed Mutagenesis Kit (NEB # E0554S).

To make pTet-Off All-In-One plasmids, pcDNA3.1(+)/no uORF nLuc plasmid was subjected to two rounds of mutagenesis using the NEBuilder HiFi DNA Assembly Master Mix with 25 bp overhangs. First, the complete CMV promoter was replaced with the tetracycline-responsive P_{Tight} promoter from pCW57.1-MAT2A (a gift from David Sabatini; Addgene plasmid # 100521)³⁷. Second, the neomycin resistance gene coding sequence was replaced with the tTA-Advanced coding sequence from pCW57.1-MAT2A. The different uORF nLuc inserts were then subcloned into this pTet-Off All-In-One backbone at SacI and XbaI sites. The 133 bp chimeric intron from pCI-neo (Promega # E1841) was inserted into the nLuc ORF by using the Q5 Site-Directed Mutagenesis Kit.

All oligonucleotides were obtained from Integrated DNA Technologies. TOP10 *E. coli* cells were used for all plasmid propagation and cloning. Reporters and any mutated sites were fully Sanger sequenced at The Ohio State Comprehensive Cancer Center Genomics Shared

Resource (OSUCCC GSR). All plasmids are available upon request and will be deposited into Addgene upon publication.

***In vitro* transcription**

Reporter mRNAs were synthesized using linearized plasmids as templates for run off transcription with T7 RNA polymerase as previously described³⁴ with the single exception that XbaI was used to linearize all plasmids. All mRNAs were transcribed at 30°C for 2 hrs using HiScribe T7 High Yield RNA Synthesis Kit (NEB # E2040S) and were co-transcriptionally capped and post-transcriptionally polyadenylated. Non-IRES mRNAs were capped the 3'-O-Me-m7G(5')ppp(5')G anti-reverse cap analog (NEB # S1411L). IRES mRNAs were capped with the A(5')ppp(5')G cap analog (NEB # S1406L). Post-transcriptional polyadenylation was performed using *E. coli* Poly(A) Polymerase (NEB # M0276L). mRNAs were purified using the Zymo RNA Clean and Concentrator-25 (Zymo Research # R1018), eluted in RNase-free water, aliquoted in single use volumes and stored at -80°C.

***In vitro* translation and luciferase assay**

10 µL *in vitro* translation reactions were performed in the linear range using 3 nM mRNA in the Flexi Rabbit Reticulocyte Lysate (RRL) System (Promega # L4540) with final concentrations of reagents at 30% RRL, 10 mM amino acid mix minus Leucine, 10 mM amino acid mix minus Methionine, 0.5 mM MgOAc, 100 mM KCl, and the addition of 8 U murine RNase inhibitor (NEB # M0314L)³⁴. Reactions were incubated for 30 min at 30°C, terminated by incubation on ice, and then diluted with 40 µL Glo Lysis Buffer (Promega # E2661). 25 µL of diluted reaction was mixed with 25 µL of prepared Nano-Glo Luciferase Assay System (Promega # N1120) for 5 min in the dark on an orbital shaker. Luminescence was measured using a Promega GloMax Discover Microplate Reader.

Fluorescent ribosome toeprinting

60 μ L *in vitro* translation RRL reactions (same final concentrations of reagents as above) were pre-incubated with 50 μ M lactimidomycin (5 mM stock in DMSO) for 10 min at 30°C then placed on ice. 25 nM capped and polyadenylated mRNA was added (increased concentration was important to detect weaker signals), gently mixed, and incubated for an additional 10 min at 30°C to allow inhibited 80S ribosomes to form after start codon recognition. To each reaction, 20 μ L 5X AMV RT buffer (final: 50mM Tris-HCl (pH 8.3), 50 mM KCl, 10 mM MgCl₂, 0.5 mM spermidine, 10 mM DTT), 10 μ L 10 μ M 5'-FAM labeled-reverse primer (20 nt), 2 μ L 25mM complete dNTP set (final of each dNTP at 0.5 mM), 6 μ L nuclease-free water, and 2 μ L AMV Reverse Transcriptase (stock at 20-25 U/ μ L) was added and reverse transcriptase (RT) was allowed to progress for 35 min at 30°C. The higher MgCl₂ concentration in the RT reaction inhibits new initiation complex formation. Control reactions with 25 mM reporter mRNA in water were treated identically and were used to determine background from the RT reaction. FAM-labeled cDNA was extracted by transferring the 100 μ L RT reaction to a new microcentrifuge tube with 150 μ L nuclease-free water and adding 250 μ L saturated Phenol:Chloroform:Isoamyl Alcohol (25:24:1), pH 8. After vigorous mixing for 1 min, samples were centrifuged at room temperature at 16,000 rcf for 5 min. The top aqueous phase was transferred, and re-extracted with saturated Phenol:Chloroform:Isoamyl Alcohol (25:24:1), pH 8. The final aqueous supernatant was then concentrated using the Zymo DNA Clean and Concentrator-5 using a 7:1 ratio following the manufacture's recommendation. FAM-labeled cDNA was eluted in 7 μ L nuclease-free water. 5 μ L of each eluate was mixed with 10 μ L Hi-Di Formamide (Thermo # 4440753), spiked with a LIZ 500 size standard, and subjected to fragment analysis using Applied Biosystems 3130xl Genetic Analyzer with POP-7 polymer with all fragments being reported. To determine which signals were caused by inhibited 80S ribosomes at start codons, signal from the control samples (RNA in water + RT reaction) were subtracted from the reactions with RRL and inhibitor. Primer sequence is included in the Supplemental Table 1.

Cell culture, transfection, and luciferase assay

HeLa cells were obtained from ATCC and maintained in high glucose DMEM supplemented with 10% heat-inactivated FBS, 1% penicillin-streptomycin, and 1% non-essential amino acids in standard tissue culture-treated plastics. HeLa cells were seeded 24 hr before transfection so that on the day of transfection they were at 50% confluency. ViaFect (Promega # E4982) was used at a 3:1 ratio with 1 µg total plasmid (500 ng nLuc plasmid + 500 ng pGL4.13) in 100 µL in Opti-MEM (Thermo Fisher # 31985062). For 96-well plates, HeLa cells were transfected with a total of 100 ng (10 µL of the transfection mix). 24 hr post transfection, media was aspirated, and cells were lysed in 100 µL Glo Lysis Buffer (Promega # E2661) for 10 min on an orbital shaker. 25 µL of lysate was then mixed with 25 µL of ONE-Glo (Promega # E6120) or 25 µL of prepared Nano-Glo Luciferase Assay System (Promega # N1120) and detected as described above. nLuc signal was then normalized to FFLuc signal of the same sample to normalize for transfection efficiency.

Tet-Off System and mRNA decay measurements

HeLa cells were seeded and maintained in complete media as described above, but supplemented with 10% Tet-approved FBS (Thermo Fisher # A47364-01). 24 hr post seeding in a 10 cm plate, 50% confluent cells were transfected with 6 µg of total plasmid (3 µg pTet-Off All-In-One plasmids + 3 µg pGL4.13) using ViaFect. 24 hr post transfection, cells were trypsinized, diluted, and seeded in five 12-well dishes. 48 hrs later, when cells were ~75% confluent, media was replaced with media containing 2 µg/mL doxycycline (MP Biomedicals # 195044) (stock at 1 mg/mL in water) in the dark. At the indicated time points, total RNA was extracted using TRIzol (Thermo Fisher # 15596018) following the manufacture's recommendations. 500 ng of total RNA was then DNase-treated with amplification grade DNase (Thermo Fisher # 18068015). The entire final 11 µL DNase reaction was then used to synthesize cDNA with oligo-

dT and random hexamers using the iScript Reverse Transcription Supermix for RT-qPCR (Bio-Rad # 1708841) following the manufacture's protocol. cDNA was then diluted 1:100 and 1.5 μ L was used per 15 μ L reaction with iTaq Universal SYBR Green Supermix (Bio-Rad # 1725122) and 250 nM primers (final) on a Bio-Rad CFX Connect Real-Time PCR Detection System using Bio-Rad CFX Maestro software to calculate expression levels. Reporter levels were normalized to RPS17 and half-lives were calculated using first order exponential decay trend lines, calculated by non-linear regression in GraphPad Prism 9.1.2. The 95% confidence intervals were plotted along the mean of three biological replicates. Reverse transcriptase minus reactions were used to confirm less than 2% of reporter signal is from contaminating plasmid DNA. All primer sequences are available in **Supplemental Table S1**.

Bioinformatic analysis of uORF length and mRNA decay

mRNA half-lives measured using BRIC-seq was obtained from published literature^{26,27,38}. Custom python scripts were written to first calculate the cumulative uORF length in each mRNA and then assigned it to the previously defined half-life. Both scripts have been deposited in GitHub (github.com/michaelkearse/uORF_Half-life). The scripts utilize the RefSeq Transcript and RefSeq Reference Genome Annotation files for human genome build 38 from NCBI for reference. If a gene had multiple transcripts listed, then the longest transcript (usually isoform 1) was used. Only AUG-encoded uORFs were determined. Transcripts were then binned by cumulative uORF length in five codon increments with at least 100 mRNAs in each bin. The total sample number per bin is included in **Supplemental Table S2**, along with the cumulative uORF length and half-life for each mRNA.

ACKNOWLEDGEMENTS

Experiments were conceived and performed by PJR and MGK with input and help from LPB. The bioinformatics analysis was performed by JAS with input from AHMB. The manuscript was written by PJR and MGK with input from JAS, LPB, and AHMB. PJR was supported by NIH grants T32GM086252 and T32GM141955. This work was supported by NIH grant R00GM126064 (to MGK). We thank members of the Kearse lab for critically reading the manuscript. We also thank Christine Daugherty at The Ohio State Comprehensive Cancer Center Genomics Shared Resource (OSUCCC GSR) for her critical help with the fluorescent toeprinting analysis. The OSUCCC GSR is supported by NIH grant P30CA016058.

Figure 1

A

B

C

D

Figure 1. A small uORF with three start codons in perfect context is able to sequester all scanning initiation complexes. A) Design of re-initiation specific nanoLuciferase (nLuc) reporters used in this study. A 16 nt spacer between the variable-sized uORF and nLuc ORF

allows specific detection of re-initiation. B) Schematic of ribosome toeprinting with FAM-labeled primers to detect sites of initiation with lactimidomycin pre-incubation. C-D) Ribosome toeprinting of 80S ribosomes after start codon recognition on small uORF nLuc reporter mRNA (C) and mutated uORF nLuc reporter mRNA (D). Signal from unused primer is seen at 20 nt. Signal from duplicate samples is shown in black and red.

Figure 2

Figure 2. Translation re-initiation is more efficient after small uORFs *in vitro* and in HeLa cells. A-B) Response of nLuc reporters that harbor a small, mutant, large, or truncated uORF from *in vitro* translation (A) and in HeLa cells (B). n=3 biological replicates. Bar represents the mean. C) Insertion of the P2A “ribosome skipping motif” (gray) was used to assess the relative translation efficiency of reporters that harbored a 3XAUG start codon sequence without and with

the large HTGFP (blue) sequence upstream of the nLuc coding sequence (purple). D) Relative nLuc activity of the small and larger ORF reporters from *in vitro* translation. Shaded in blue is the signal of the large uORF-P2A-nLuc reporter normalized for ORF length. n=3 biological replicates. Bar represents the mean. Comparisons were made using a two-tailed unpaired *t*-test with Welch's correction.

Figure 3

A

B

C

Figure 3. uORFs translated by IRESs that require less initiation factors permit less re-initiation. A) Schematic of A-capped IRES-mediated re-initiation reporters. A stable hairpin was insert upstream of the IRES to block scanning ribosomes B) Requirements of canonical initiation and class I-IV viral IRES-mediated initiation. C) Response of canonical initiation and viral IRES-dependent nLuc reporters without and with small uORFs from *in vitro* translation. n=3 biological replicates. Bar represents the mean. PV=poliovirus; EMCV=encephalomyocarditis virus; HCV=hepatitis C virus; CrPV IGR=cricket paralysis virus intergenic region; PIC=pre-initiation complex; eIF=eukaryotic initiation factor. Comparisons were made using a two-tailed unpaired *t*-test with Welch's correction.

Figure 4

Figure 4. uORF length has minimal effect on mRNA stability in cells. A-D) A Tet-Off system triggered with 2 μ g/mL doxycycline (dox) was used to determine reporter mRNA half-lives in

HeLa cells. n=3 biological replicates. A non-linear regression was used to calculate the mRNA half-lives and is shown as the line with the 95% confidence interval included as a watermark. E) Transcriptome-wide comparison of cumulative uORF length and mRNA half-life. Bar represents the mean $\pm$ 95% confidence interval. One-way Welch's ANOVA was used to compare between cumulative uORF length bins.

Supplemental Figure S2

Supplemental Figure S2. Less translation re-initiation after large uORFs is not strictly sequence specific. A) The large uORF sequence described in **Fig. 1** was switched from HT-GFP to Firefly Luciferase (FFLuc). Three AUG start codons in perfect context was used to trap all scanning initiation complexes at the uORF. B) Response of nLuc reporters that harbor a large (FFLuc) or truncated uORF (FFLuc) from *in vitro* translation. Similar repression and rescue

were seen here with FFLuc as the large uORF as observed with HT-GFP sequence in **Fig. 2**.

n=3 biological replicates. Bar represents the mean. Comparisons were made using a two-tailed unpaired *t*-test with Welch's correction.

Supplemental Figure S3

Supplemental Figure S3. uORF length control of re-initiation is seen with uORFs

harboring 10 consecutive AUG start codons. Response of nLuc reporters that harbor a small, mutant, large, or truncated uORF from *in vitro* translation. All uORFs had 10 consecutive AUG start codons as described in **Supplemental Fig. S1** (instead of the three AUG start codons in perfect Kozak context in **Fig. 1**). Large and truncated uORFs using the FFLuc sequence are clearly labeled from those that used the original HT-GFP sequence. n=3 biological replicates. Bar represents the mean. Comparisons were made using a two-tailed unpaired *t*-test with Welch's correction.

Supplemental Figure S4

Supplemental Figure S4. uORF length has minimal effect on mRNA stability in cells. A)

Transcriptome-wide analysis of cumulative uORF length and mRNA half-life from Tani *et al.*

(2012). One-way Welch's ANOVA was used to compare between cumulative uORF length bins.

B) Model of uORF length controlling re-initiation and mRNA stability.
