Abstract

Bite force is a decisive performance trait in animals because it plays a role for numerous life history components such as food consumption, inter- and intraspecific interactions, and reproductive success. Bite force has been studied across a wide range of vertebrate species, but only for 20 species of insects, the most speciose animal lineage. Here we present the insect bite force database with bite force measurements for 654 insect species covering 111 families and 13 orders with body lengths ranging from 4.2 - 180.1 mm. In total we recorded 1906 bite force series from 1290 specimens, and, in addition, present basal head, body, and wing metrics. As such, the database will facilitate a wide range of studies on the characteristics, predictors, and macroevolution of bite force in the largest clade of the animal kingdom and may serve as a basis to further our understanding of macroevolutionary processes in relation to bite force across all biting metazoans.

Background & Summary

23

24 Bite force is a performance trait which may decide on an animal's ability to acquire food, win

25 inter- and intra-specific fights and successfully reproduce[1–5]. In vertebrates, maximum bite

26 forces are well studied across a wide diversity of taxa such as bony fishes[6,7], crocodilians (e.g.

27 [8]), birds (e.g. [9]), turtles (e.g. [10]), squamates (e.g. [11,12]), frogs[13], marsupials[14], and mammals (e.g.

28 [15–18]).

29 Fundamental knowledge on the variation, predictors and evolution of bite forces within the

30 omnipresent insects is, however, lacking. Even though more than half a million insect species

31 belong to orders that possess biting-chewing mouthparts[19,20], existing literature only yields

32 bite force measurements on five dragonflies[21,22], one cockroach[23], and 14 beetles[24,25]. This is

33 despite the fact that biting-chewing insects include the most destructive plant eating animals

34 and occupy crucial roles in the world's ecosystems as soil-building detritivores[26].

35 So far, measuring bite forces of insects was hampered by their small size, but the recently

36 published measurement setup "forceX"[27] overcame this limitation to some extent by allowing

37 minimally invasive *in vivo* bite force measurements of animals with gape sizes more than ten

38 times smaller than previous setups (e.g. [28]). Using forceX, we measured bite forces of 654

39 insect species from 111 families and 13 orders, collected on four continents and from

40 numerous breeding cultures. Instead of gathering maximum force values only, as most

41 previous bite force studies have done (but see [25,23,21,22,29]), we also recorded force curves. In

42 addition, the bite force database contains head, wing and body metrics of each specimen to

43 assess morphological predictors for bite force in insects. Thus, the database will facilitate

44 investigations on the macroevolution of maximum bite force, bite lengths, bite frequencies,

45 muscle activation patterns, and bite curve shapes across the megadiverse insects and will

46 facilitate comparisons with all biting metazoan taxa.

Methods

Collection and material

A total of 1290 insect specimens representing 654 species from 111 families and 13 orders were collected in Australia, China, Denmark, France, Germany, Greece, Panama and Slovenia using light traps, insect nets, pitfall traps, or directly by hand. All specimens were collected under the respective regulations in effect (see Acknowledgements). Additionally, we measured specimens from numerous scientific, private and commercial insect breeders and traders (Online-only Table 1 and Acknowledgements).

Size measurements

Head width, head length, head height, thorax width, forewing length and body length measurements were performed to the nearest 0.01 mm using a digital caliper (77001, Wentronic GmbH, Braunschweig, Germany). For the head width, the longest distance from left to right was measured, including protruding eyes if applicable (Fig. 1a). Head height in orthognathous insects was measured from the clypeo-labral ridge to the dorsal end of the head (Fig. 1a,b). In prognathous insects, head length was measured from the clypeo-labral ridge to the posterior end of the head (Fig. 1c). Thorax width was measured on the prothorax (Fig. 1d) and excluded lateral protrusions as found e.g. in many cockroaches and praying mantises. Body length measurements excluded cerci, ovipositors, or other abdominal appendages (Fig. 1e).

Bite force measurements

All measurements were carried out with the metal-turned version of the forceX setup as described in [27]. In short, life and conscious animals were held between two fingers, rotated by 90° along their body axis and allowed to voluntarily bite on the tip elements of the forceX.

4

70 Different tip element designs[27] and distances between them were used to accommodate

71 different animal gape sizes. During measurements, animals were observed through the Junior

72 Stereo 3D microscope (Bresser GmbH, Rhede, Germany) that is part of the forceX setup to

73 ensure that gape sizes are suitable and that the insects bite at the edge of the tip elements so

74 that the ratio of the forceX lever remains at a constant 0.538[27,30]. We also checked if the

75 animals bit with the distal-most incisivi of their mandibles to ensure that measurements

76 remain comparable[30]. Non-distal bites or wrongly placed bites on the tip elements were

77 discarded. If animals did not start biting by themselves, we used the tip element protrusions

78 to insert the tip elements between the mandibles and/or used a fine brush to touch the

79 animal's cerci, head or abdomen[23]. Amplified analogue voltage signals were converted to a

80 digital signal by a 12-bit USB data acquisition device (U3-HV, LabJack Corporation, Lakewood,

81 Colorado, US) and recorded with the LJStreamUD v1.19 measurement software (LabJack

82 Corporation) on a computer.

83 Data curation

84 Subsequent data curation was performed in the software environment 'R' v.4.03[31] using the

85 package 'forceR' v.1.0.0[27]. Since the forceR package was written to analyse data generated

86 with the forceX setup, we used, if not stated otherwise, the default settings of the package

87 functions. First, time series were converted from the output format of LJStreamUD to a *.csv

88 file containing only a time and a voltage column (without changing measurement values) using

89 the forceR function 'convert_measurement()'. Then, all measurements were manually

90 cropped using 'crop_measurement()' to exclude regions without bite data at the beginning

91 and end of each measurement. Next, 'amp_drift_corr()' was used to correct for the logarithmic

92 drift of the analogue charge amplifier (see Rühr and Blanke [27] for details). When using the high

93 amplification setting (20 V/N) to amplify the miniscule voltage signals of the piezoelectric force

94 transducer at small bite forces, the zero-voltage-line ('baseline') may drift notably during a

95 measurement. Therefore, a PDF file depicting all input raw data and their amplifier drift-

96 corrected data graphs (available at Zenodo, s. Data Records) was visually inspected, and, if

97 necessary, the function 'baseline_corr()' was used in its automatic mode to correct for this

98 drift. In some of these cases, however, especially when the test animals showed long, plateau-

99 like bite curve shapes, the automatic mode of 'baseline_corr()' failed to find the baseline, and

100 the manual mode was used. All corrections can be retraced in the PDF file and reproduced

101 using the log files that were created during corrections and which are stored at Zenodo. With

102 the function 'reduce_frq()' we then reduced the sampling rate of all time series to 200 Hz, a

103 value found to be sufficient to represent insect bite force curves[25,23,22,22] to reduce the amount

104 of data for further analyses. As a last curating step, voltage values were converted into force

105 data [N] with the forceR function 'y_to_force()' that considers the amplification level of each

106 measurement and the lever mechanics of the measurement system. Online-only Table 1

107 shows all measurement settings, taxonomic classifications and information on which

108 correction procedures have been performed on which measurements.

Maximum force value extraction for specimens and species

110 To extract maximum force values of each specimen and each species and calculate the

111 standard deviations of these values we used the function 'summarize_measurements()' of

112 forceR and custom code, heavily on the packages 'dplyr' v.1.0.7[32]. We then plotted the log10-

113 transformed average maximum bite force per specimen (grey dots in Fig. 2) and per species

114 (black dots) against the log10-transformed average body length (Fig. 2a) and head width (Fig.

115 2b) using 'ggplot2' v.3.3.5[33] and 'ggExtra' v.0.9[34]. Linear regressions through the log10-

116 transformed species-wise data showed significant allometric relationships between body size

117 and head width ($p < 0.001$) with explanatory values of $r^2 = 0.43$ and $r^2 = 0.56$, respectively. Due

118 to the expected logarithmic releationship between size and bite force[35], means were

119   calculated as geometric means. Calculations with the regular mean, however, yielded similar

120   results ($p < 0.001$, $r^2 = 0.44$ and $r^2 = 0.56$; Supplementary Figure 1).

121   ## Comparison to previous insect bite force measurements

122   Previous studies on insect bite forces covered maximum bite force values for 20

123   species[24,23,21,22]. To check if these measurements follow similar allometric slopes as our data,

124   we extracted all available insect bite force data from the literature and added them to the

125   scatterplot in Figure 2b. We then tested if our data and the literature data differ in their

126   allometric slopes by comparing a linear model with the null hypothesis of different slopes

127   (log10(bite.force)$\sim$ log10(head.width) * source) versus a linear model with the null hypothesis

128   of common slopes (log10(bite.force) $\sim$ log10(head.width) + source). Both model fits were

129   compared with an ANOVA to find out if they differ significantly.

130   ## Assessment of geographical coverage

131   Climate zone data (Köppen–Geiger classification system[36–38]) was gathered for each species

132   based on the GPS coordinates of its collection localities (Online-only Table 1) with the function

133   'LookupCZ()' of the R package 'kgc' v.1.0.0.2[39]. Percentages of species in the database for each

134   country and climate zone were calculated.

135   ## Assessment of phylogenetic coverage

136   To assess the phylogenetic coverage of the bite force database we compared the number of

137   species with database entries to the number of species listed by the Open Tree of Life[40],

138   accessed on 2022/02/05 with the function 'tol_node_info()' of the package 'rotl' v.3.0.11[41].

139   Comparisons were carried out for all insect orders and families that are present in the bite

140   force database.

Data Records

All raw measurements, the cleaned time series, and the PDF and log files created during the conversion of the raw data to the final database are available in comma-separated format at Zenodo: https://doi.org/10.5281/zenodo.5782922). Online-only table 1 is also stored in the same repository.

Technical Validation

Visual inspection of the scatter plot of bite force against head width (black dots in Fig. 2b) and all literature data points (orange diamonds) revealed that the literature data lies close to the regression through all data points of our database. This impression is corroborated by the comparison of the allometric slopes of the insect bite force database and the literature data, which yielded no statistically significant difference (ANOVA: $F = 0.102$, $p = 0.75$).

Geographical assessment of the collected animals showed that most species of the insect bite force database were collected in Australia (30.7%), Germany (19.1%), and Panama (16.4%). 23.2% of the species were obtained from breeding cultures. The remaining 10.6% of the species were collected in Greece, Slovenia, France, China, and Denmark. Climate region assessment revealed that most species were collected in temperate (54%) and tropical (43.2%) regions. 2.8% came from dry and continental regions combined (Fig. 3b). We did not consider the original geographic distribution of those species obtained from breeding cultures.

A total of 13 biting-chewing insect orders are present in the database (Fig. 3d). We could not obtain life animals from the orders Zoraptera and Grylloblattodea. Bite force measurements of the few species of Plecoptera, Mecoptera, and Trichoptera that were available failed because no voluntary biting could be elicited in these specimens. We did not attempt measuring available representatives of Psocoptera and the biting-chewing "mandibulate archaic moths" (Lepidoptera: Micropterigoidea) due to their minute size. The assessment of

8

165   phylogenetic coverage of the orders and families showed that most families are represented

166   by less than one species entry per 100 estimated species (Fig. 3c). While orders were sampled

167   in proportion to their taxonomic diversity (Fig. 3d), we were only able to measure at least 1%

168   of the described species in Mantophasmatodea, Phasmatodea and Mantodea (dots left of

169   dashed line in Fig. 3a). Accordingly, bite forces of only a fraction of all insect species were

170   measured so far. Nevertheless, the database exceeds all previous studies combined in species

171   numbers (30-fold in insects, 3.5-fold in amniotes), marking just the beginning of research on

172   this performance trait in the most species-ridge metazoan clade.

173   ## Usage Notes

174   The forceR package[27] was used to create the insect bite force database, which contains

175   cleaned measurement time series and maximum bite forces of insects. The same package may

176   be used to expand the scarce knowledge on insect bite forces by tackling questions regarding

177   the evolution of bite lengths, frequencies, and bite curve shapes by semi-automatically

178   extracting individual bite curves from these measurements. Additionally, the maximum bite

179   force values presented in Online-only table 1 can be used for a wide range of in-depth studies

180   on the morphological and ecological predictors and macroevolution of this important

181   performance trait in the megadiverse insects.

182   ## Code Availability

183   The R code to convert the raw measurements into the final database and to create all tables

184   and figures used in this publication can be found at https://github.com/Peter-T-

185   Ruehr/Insect_Bite_Force_Database.
