13

ABSTRACT

14 Animal domestication typically affected numerous polygenic quantitative traits, such as behaviour,
15 development and reproduction. However, uncovering the genetic basis of quantitative trait variation is
16 challenging, since it is probably caused by small allele-frequency changes. To date, only a few causative
17 mutations related to domestication processes have been reported, strengthening the hypothesis that small
18 effect variants have a prominent role. So far, the studies on domestication have been limited to the detection
19 of the global effect of domestication on deleterious mutations and on strong beneficial variants, ignoring
20 the importance of variants with small selective effects. In addition, very often, the study of the effects of
21 selection are conducted on genome sequences that contain a non-negligible fraction of missing data,
22 especially in non-model organisms. Hence, appropriate methods to account for these positions are needed.
23 To overcome these difficulties, here we propose to estimate the proportion of beneficial variants using the
24 asymptotic MacDonald-Kreitman (MK) method based on estimates of variability that summarizes the site
25 frequency spectrum (SFS) while accounting for missing data and use them to perform an Approximate
26 Bayesian Computation (ABC) analysis to infer the Distribution of Fitness Effects (DFE) of each population.
27 We applied this approach to 46 genome sequences of pigs from three different populations, one wild and
28 two domestics, with very different demographic histories and selective pressures. The obtained results
29 showed that domestic and wild pig populations do not differ in nonsynonymous fixed mutations. Therefore,
30 differences in α estimation among breeds are determined by their polymorphisms. The comparison of α
31 for total and exclusive mutations suggests that the different domestic populations have suffered recent
32 divergent changes in their functional versus neutral polymorphisms ratio, while the wild population is
33 compatible with $\alpha=0$. Besides, the DFE inferred with ABC indicates that both wild and domestic pigs
34 display a large number of deleterious mutations at low frequency and a high number of neutral and/or
35 nearly-neutral mutations that may have a significant effect on the evolution of domestic and wild
36 populations. In addition, models not considering beneficial mutations have higher posterior probabilities,
37 suggesting that beneficial mutations are difficult to detect or are scarce. Indeed, for all three populations,
38 the median proportion of the strong favourable mutations are very low ($\leq 0.1\%$) in those models that
39 includes positive selection, with the average values of weak beneficial mutations around 0.6% for wild boar
40 and 0.8-1.0% for the domestic pigs. Lastly, the analysis based on exclusive mutations showed that recent
41 demographic changes may have severely affected the fitness of populations, especially that of the local
42 Iberian breed.

46 INTRODUCTION

47 Domestic animal histories are evolutionary experiments that have often lasted for millennia
48 resulting in dramatic phenotypic changes to suit human needs. In addition, domestic species can
49 be structured into subpopulations (breeds) that are partly or completely genetically isolated and
50 can display a wide catalogue of specific phenotypes. Therefore, they offer a very valuable material
51 of utmost interest to study the interplay between demography and accelerated adaptation.
52 However, as their demographic history can be quite complex, many events remain unknown or
53 poorly documented nowadays.

54 The pig (*Sus scrofa*) is a particularly interesting species because of its domestication history and
55 its relatively well-annotated genome. *S. scrofa* originated in Southeast Asia ~1-4 MYA and spread
56 throughout Eurasia ~0.2-1.2 MYA, colonizing all climates except the driest (Frantz et al. 2013,
57 Zhang et al. 2021). Subsequently, the pig was domesticated from local wild boars (WB)
58 independently in both Asia and Europe ~9,000 years ago. To complicate the story, modern
59 European domestic pig breeds were crossed with Asian domestic pigs during the late 17th century
60 and onwards. In breeds such as Large White (LW), approximately 30% of the genome is estimated
61 to be of Asian origin (Bosse, Megens, Madsen, et al. 2014). Nevertheless, some local European
62 breeds, such as the Iberian breed (IB), were spared genetic contact with Asian pigs and no evidence
63 of genetic introgression has been found in this breed (Alves et al. 2003, Esteve-Codina et al. 2013).
64 Moreover, domestic breeds have different recent demographic histories. For instance, the IB breed
65 suffered a dramatic reduction of its effective population size during the last century (Alves et al.
66 2006), whereas many commercial breeds such as Duroc or LW have been introgressed with Asian
67 pigs (Bosse, Megens, Frantz, et al. 2014).

68 Differences in the effective population size, demographic histories and artificial selective pressures
69 between pig breed or populations could result in differences among their evolutionary rates. In
70 addition to possible differences in the evolutionary rates between populations, there may be
71 differences in the evolutionary rate between genes within genomes. For instance, it is known that
72 the strength of the selection is affected by the position of the genes in the networks in which they
73 participate. Genes that are more central in a network and are more connected with other genes are
74 more evolutionarily constrained, while peripheral genes are more prone to be under adaptive
75 selection (Fraser et al. 2002; Hahn and Kern 2005; Montanucci et al. 2011; Alvarez-Ponce and

76 Fares 2012). Furthermore, it has been observed that the evolutionary rate, within a metabolic
77 pathway, increases as we move downstream, possibly because upstream genes are more
78 pleiotropic, since they are involved in more functions and hence, these genes are probably more
79 conserved (Rausher, Miller, and Tiffin 1999; Riley, Jin, and Gibson 2003; Livingstone and
80 Anderson 2009; Ramsay, Rieseberg, and Ritland 2009).

81 So far, the nature of the underlying genetic changes caused by domestication and ensuing artificial
82 breeding is still under debate. While the most prevalent view is that regulatory changes have been
83 targeted (Anderson 2013), several other studies underline the influence of protein coding changes
84 (Rubin et al. 2012). Some authors have reported an increase in the rate of deleterious mutations in
85 domestic pigs compared to their wild counterparts (Cruz, Vilà, and Webster 2008; Renaut and
86 Rieseberg 2015; Pérez-Enciso et al. 2017; Leno-Colorado et al. 2017). Others, as in Makino et al.
87 (2018) detected a general pattern of reduction of variability in domestic populations in relation to
88 their wild counterpart, and a higher nonsynonymous/synonymous ratio across the frequency
89 spectrum. These patterns were compatible with the effect of strong bottlenecks in domestic
90 populations and the higher accumulation of deleterious mutations. Interestingly, the same authors
91 observed the opposite trend in pigs (e.g., higher variability levels in domestic pigs compared to
92 their wild counterpart). Moreover, most of these previous studies have focused on genes of major
93 effect with clear signals of selective sweeps. In those studies, the hallmarks of positive selection
94 were detected as valleys of reduced variation and/or population differentiation that spans relatively
95 large regions (e.g., Amaral et al. 2011, Rubin et al. 2012, Frantz et al. 2013, Wilkinson et al. 2013),
96 but also by the presence of haplotype structure and homozygosity blocks (e.g., Fang et al. 2011,
97 Bosse et al. 2012, Li et al. 2013). Some of these studies have detected recent breed specific signals
98 of selection attributed to the domestication process (Li et al. 2014, Kim et al. 2015). Nevertheless,
99 the signals were too scarce to explain the whole picture of the domestication process. Other studies
100 have tried to elucidate the effect that domestication has at the genomic scale and on the fitness of
101 individuals of domestic populations (e.g., Cruz et al. 2008, MacEachern et al. 2009, Kono et al.
102 2016, Perez-Enciso et al. 2016, Makino et al. 2018, Chen et al. 2018, Orlando and Librado 2019).
103 For instance, an excess of deleterious variants has been observed in a number of domestic animal
104 and plants (e.g., contrasting nonsynonymous versus synonymous polymorphism ratios, Chen et al.
105 2018, using the MacDonald framework, MacEachern et al. 2009, contrasting the ancestors with
106 ancient DNA, Orlando and Librado 2019, combining the frequency of polymorphisms with

107 functional effects and divergence, Kono et al. 2016, Makino et al. 2018). Kono et al. (2016) and
108 Perez-Enciso et al. (2016) found an excess of deleterious variants affecting phenotypes of interest,
109 suggesting, as we previously mention above, that protein sequence may have a stronger influence
110 than regulatory changes in the domestication process. Kono et al. (2016) also showed that null
111 alleles are uncommon in domestic animal species (also reviewed by Anderson 2013), suggesting
112 that phenotypic changes involved in domestication are produced by the accumulation of
113 consecutive mutations that modify the gene functions under selection. Finally, the possible
114 presence of beneficial mutations during the domestication process has also been reported (Perez-
115 Enciso 2016).

116
117 Here, we are interested in determining the proportion and the selective effects of protein-coding
118 variants in wild and domestic pig genomes to understand their role in the domestication process.
119 Particularly, we aimed to test the role of both new and extant mutations in the domestication
120 process and whether the phenotypes associated with domestic breeds are the product of a large
121 number of variants with weak selective effects, as suggested by previous results. To achieve this,
122 we have investigated the differential effects of selection on coding sequences at the different
123 molecular scales (gene, metabolic pathway and whole-genome) in two domestic and one wild pig
124 population using the McDonald-Kreitman framework (McDonald and Kreitman 1991, Eyre-
125 Walker 2006, Fay 2011). We also have performed forward exploratory simulations and inferred
126 the distribution of fitness effects (DFE) while taking into account the effect of different
127 demographic scenarios. Interestingly, the analysis was performed using variability estimators that
128 allow including positions with missing data (Ferretti, Raineri, and Ramos-Onsins 2012).

129 Our results support the hypothesis that changes in allele frequencies in coding variants with weak
130 positive selective effect have been relevant for pig domestication, as evidenced by a relatively high
131 number of nonsynonymous variants segregating at medium and high frequencies and by the
132 obtained estimates of the DFE in domestic pig populations.

133

134

135 MATERIALS AND METHODS

136 Biological samples

137 We analyzed a sample of 46 pig (*Sus scrofa*) genomes (Table S1). These pigs correspond to
138 European wild boars (WB, n = 20) and domestic pigs, which are represented by the Iberian
139 Guadyerbas (IB, n = 6) and Large White (LW, n = 20) breeds. The two domestic breeds were
140 selected because they have very different interesting features: IB is a local breed that has been
141 under weak artificial selection intensity and with no documented evidence of Asian introgression.
142 LW, in contrast, is a commercial breed undergoing strong artificial selection with a deliberate
143 admixture with Asian pigs (Bosse, Megens, Madsen, et al. 2014; Groenen 2016). To analyze the
144 divergence between the different breeds, we built the consensus ancestral reference sequence
145 obtained from combining the genomic information from several *Sus* species (*S. barbatus*, *S.*
146 *cebifrons*, *S. verrucosus*, *S. celebensis*, approximately 4.2 MYA of divergence) and the African
147 warthog (*Phacochoerus africanus*, around ~10 MYA of divergence) and used as an outgroup, as
148 in Bianco et al. (2015). All sequences (see reference numbers at Table S1) are available in public
149 databases: those generated in several previous works (Rubin et al. 2012; Ramírez *et al.* 2014;
150 Bianco *et al.* 2015; Frantz et al. 2015; Moon *et al.* 2015, Esteve-Codina *et al.* 2013, Leno *et al.*
151 2017) and those generated in this work (WBES0231, WBES0252, WBES0288, WBES0291 and
152 WBES0297, see Table S1). They can be downloaded from the short read archive (SRA,
153 <http://www.ncbi.nlm.nih.gov/sra>, see accession numbers in Table S1).

154

155 Mapping and genotyping analysis

156 For each pig genome, raw reads were mapped against the reference genome assembly
157 (Sscrofa10.2, Groenen et al. 2012) using *BWA mem* option (H. Li and Durbin 2009). PCR
158 duplicates were removed using *SAMtools rmdup* v. 0.1.19 (H. Li et al. 2009) and mapped reads
159 were realigned around indels with the *GATK IndelRealigner* tool (McKenna et al. 2010). Genotype
160 calling was performed with *SAMtools mpileup* and *bcftools call* v. 1.3.0 (H. Li et al. 2009) for each
161 individual separately. We set a minimum (5x) and a maximum depth (twice the average sample's
162 depth plus one) to call a SNP. Base quality was set to 20 (P -value=1e-2). Homozygous blocks
163 (regions of contiguous positions with the same nucleotide as the reference genome) were also
164 called, following the same criteria as with the SNPs (i.e., minimum and maximum coverage and

165 base quality) and using *samtools depth* utility, *BEDtools* (Quinlan 2014) and custom scripts
166 (available at <https://github.com/miguelperezenciso/NGSpipeline>, Pérez-Enciso *et al.*, 2017). This
167 resulted in a *gVCF* file per individual with the information about variant calls and non-varying
168 positions. Next, each *gVCF* file was converted into a fasta file and all fasta files were subsequently
169 merged to obtain a multividual *gVCF* file (Pérez-Enciso *et al.* 2017).

170

171 **Analysis of the population structure of the samples**

172 A principal component analysis (PCA) was performed using the total number of SNPs to explore
173 the population structure. First, genotypes were converted to alternative allele frequency, being 0
174 for the homozygous reference genotype (0/0), 0.5 for the heterozygous genotype (0/1) and 1 for
175 the homozygous alternative genotype (1/1). For cases of missing genotype (./.), these were
176 replaced by the average SNP frequency across all individuals. We used the function *tcrossprod()*
177 from R v. 3.3.1 (2016) to obtain the matrix of covariates from the matrix of frequencies. Finally,
178 we obtained the principal components from the Eigen-value decomposition with the R function
179 *eigen()*. The software ADMIXTURE (Alexander *et al.* 2009) was also applied to analyze the
180 population structure. The more suitable K was estimated using cross-validation procedure
181 (Alexander *et al.* 2009) and the Evanno's method (Evanno *et al.* 2005).

182

183 **Estimation of codon bias**

184 We have used the single reference sequence of *S. scrofa* to estimate the codon bias at gene and
185 genome level, assuming that polymorphic variants are not going to strongly modify the proportion
186 of codons at this species. We have estimated gene and genomic codon usage with the Major Codon
187 Usage statistic (MCU, the frequency of major codons among all codons in a sequence) and the
188 Effective number of codons (N_{cw}), using the python script following Fuglsang (2006). High values
189 of MCU indicate a strong bias in codon usage, while low values suggest small bias. Instead, high
190 values of N_{cw} indicate low codon bias because many codons are used. We have also calculated the
191 correlation between MCU and α estimates (see below), considering all annotated coding regions
192 and only coding regions having α values larger than zero.

193

194 **Estimation of levels and patterns of variability**

195 Genetic diversity and divergence per pig population were estimated using *mstatspop* software
196 (Nevado, Ramos-Onsins, and Perez-Enciso 2014; Bianco et al. 2015; Guirao-Rico et al. 2018,
197 available from the authors, <https://github.com/cragenomica/mstatspop>). The *multi-VCF* file was
198 converted into a *tfasta* (transposed *fasta*) file and *mstatspop* was run on i) the whole genome, ii)
199 windows of 5-Mb size, and iii) gene coding regions. Note that, given the ubiquitous presence of
200 missing data, the SFS with highest sample size that contained more coding SNPs, retained only
201 around 20-25% of total coding variants. As the aim of this work is to detect the presence of (weak)
202 beneficial selective effects and as not to lose power or bias the results of the analysis, we preferred
203 to use an alternative method that consider the whole set of SNPs. We used four different estimators
204 of nucleotide variability that takes into account missing data (Ferretti, Raineri, and Ramos-Onsins
205 2012): Watterson (Watterson 1975), Tajima (Tajima 1983), Fu&Li (Fu and Li 1993) and
206 Fay&Wu's estimators (Fay and Wu 2000). The variability was estimated for total, shared and
207 exclusive variants, being shared and exclusive nucleotide variability counted regarding to the total
208 positions (i.e., total = shared + exclusive).

209

210 **Filtering for artefactual effects**

211 A preliminary analysis of the variability showed a moderate negative correlation (~ 0.3) between
212 the levels of variability and divergence and the proportion of missing data for each gene. To
213 eliminate this artefactual correlation, we plotted the estimators of variability and divergence versus
214 the ratio of missing data and eliminated those genes that showed a ratio of missing data greater
215 than 0.3. Since this filtering was not enough to completely remove the bias, we also removed genes
216 with extreme values of variability and divergence (higher than 99% quantile of the total genes).
217 The remaining $\sim 13,500$ genes (70% of the total annotated genes) showed a low or null correlation
218 with missing data and were used in the present analysis (Table S2).

219

220 **Estimation of the proportion of adaptive variants**

221 Under the neutral model, the majority of polymorphisms segregating in a population are neutral
222 and only a small number of selected variants segregates for a short time on their way to loss or

223 fixation. Hence, most of the positive selected variants are only observed as fixed variants. In
224 addition, functional positions (nonsynonymous positions) are constrained compared to non-
225 functional positions (synonymous positions), and hence, their evolutionary ratios are smaller. In
226 the neutral scenario, polymorphism and divergence (excluding the adaptive fixed variants) are
227 proportional to the mutation rate and to the constriction factor in the case of nonsynonymous
228 positions (McDonald and Kreitman 1991, Eyre-Walker 2006, Fay 2011). That is:

$$229 \quad \frac{\theta_n}{\theta_s} = \frac{(1 - \alpha)K_n}{K_s},$$

230 *(Equation 1)*

231 where θ_n is the nonsynonymous variability, θ_s is the synonymous variability, K_n is the
232 nonsynonymous divergence, K_s is the synonymous divergence and α is the proportion of adaptive
233 variants that have been fixed. To estimate the proportion of nonsynonymous substitutions that are
234 adaptive (α) the previous expression is reordered (e. g., Eyre-Walker 2006):

$$235 \quad \alpha = 1 - \frac{K_s \theta_n}{K_n \theta_s}$$

236 *(Equation 2)*

237 A higher ratio of nonsynonymous to synonymous divergence versus polymorphisms suggests that
238 positive selection has fixed adaptive variants ($\alpha > 0$) and the opposite case ($\alpha < 0$) suggests the
239 presence of deleterious mutations segregating in the population.

240 If we consider that weak deleterious mutations are segregating in the population, we expect that
241 their relative proportion will be higher at lower frequency variants and low or zero for fixed
242 deleterious mutations. Following the same notation as in equation 2:

$$243 \quad \frac{\theta_{in}(1 - \beta_i)}{\theta_{is}} = \frac{(1 - \alpha - \beta_d)K_n}{K_s},$$

244 *(Equation 3)*

245 where i refers to the frequency at which the calculation of variability is estimated, β_i is the
246 proportion of weakly deleterious polymorphic mutations at frequency i , β_d is the proportion of
247 weakly deleterious fixed mutations. $\beta_d < \beta_i$ was assumed at any frequency. Then, solving for the
248 proportion of fixed adaptive variants (α):

249
$$\alpha = 1 - \beta_d - (1 - \beta_i) \frac{K_s \theta_{in}}{K_n \theta_{is}}$$

250 *(Equation 4)*

251 We see that in case of calculating α without considering the effects of deleterious mutations, this
252 would be underestimated depending on the frequency at which the estimates of variability are
253 calculated. If we assume that the deleterious variants would hardly be fixed, a good estimator of α
254 using equation 2 would be the one that estimates variability based on high frequencies, as it would
255 hardly contain deleterious mutations. This is in agreement with the asymptotic arguments used in
256 Messer and Petrov (2013) and implemented in Haller and Messer (2017).

257
258 Similarly, if we also consider that weak positively selected variants are segregating in the
259 population, we expect that their relative proportion, compared to neutral ones, is higher at higher
260 frequencies:

261
$$\frac{\theta_{in}(1 - \beta_i - \gamma_i)}{\theta_{is}} = \frac{(1 - \alpha - \beta_d - \gamma_d)K_n}{K_s},$$

262 *(Equation 5)*

263 where γ_i is the proportion of weakly advantageous polymorphic mutations at frequency i , and γ_d is
264 the proportion of weakly advantageous fixed mutations. Again, solving for the proportion of fixed
265 adaptive variants ($\alpha + \gamma_d$):

266
$$\alpha + \gamma_d = 1 - \beta_d - (1 - \beta_i - \gamma_i) \frac{K_s \theta_{in}}{K_n \theta_{is}}$$

267 *(Equation 6)*

268 In this case, the presence of adaptive variants segregating in the population would affect the
269 estimates of variability based on high frequency variants when using equation 2, which would
270 result in an underestimation of the proportion of fixed adaptive variants (α). Note that adaptive
271 variants stabilized at intermediate frequencies, which can be an important source of adaptation
272 considering the infinitesimal model, are not considered in this approach.

273

274 If we focus on the effects of polymorphic weakly selected mutations, equation 5 suggests that the
275 ratio of nonsynonymous to synonymous polymorphisms would increase due to mutations having
276 both positive and negative effects. It is expected that the number of mutations with negative
277 selection coefficients would rapidly decrease as we move to intermediate and high frequencies,
278 while the opposite trend is expected for mutations with positive selection coefficients. Hence,
279 higher ratios of nonsynonymous to synonymous polymorphisms at higher frequencies may be
280 explained by the presence of advantageous mutations segregating in the population.

281
282 Furthermore, in cases where two populations are from the same species and there are no fixed
283 mutations between them (e.g., they have equal divergence ratios versus the outgroup), we can
284 estimate the possible differential effect of the selection (positive and negative together) at any
285 frequency between populations from the ratios of synonymous to nonsynonymous polymorphisms
286 of the two populations ($R_{\beta\gamma_i}$):

$$287 \quad \frac{\theta_{in1}(1 - \beta_{i1} - \gamma_{i1})}{\theta_{is1}} = \frac{\theta_{in2}(1 - \beta_{i2} - \gamma_{i2})}{\theta_{is2}}$$

288 and

$$289 \quad \frac{(1 - \beta_{i1} - \gamma_{i1})}{(1 - \beta_{i2} - \gamma_{i2})} = \frac{\theta_{is1}\theta_{in2}}{\theta_{in1}\theta_{is2}} = R_{\beta\gamma_i}$$

290 *(Equation 7)*

291 In addition, a comparison of the $R_{\beta\gamma_i}$ values calculated using different variability estimators
292 (hereafter $R_{\beta\gamma_i}$ pattern) can be used to inform about the effects of selection. For example, values
293 over 1 indicate that the population 2 has a higher ratio of nonsynonymous to synonymous
294 polymorphisms compared to population 1, either produced by an accumulation of deleterious or
295 of beneficial polymorphisms. Importantly, different demographic effects (e.g., bottlenecks)
296 together with the presence of mutations with small selective effects may also disturb the ratios of
297 variability and hence must be considered when interpreting the results. We include a couple of
298 possible scenarios that can account for possible patterns: (i) after split of two the two populations,
299 both populations have the same population size, but population 1 is affected by the action of
300 positive selection on a quantitative trait (polygenic effect), which causes an increase in the
301 frequencies of some of its variants without getting fixed. Under this scenario, we expect a $R_{\beta\gamma} >$

302 1 when this is calculated based on high frequencies. (ii) after split of two the two populations, the
303 population 2 remains equal population size as before the split and the population 1 suffers a
304 reduction in its effective population size, which causes that the slightly deleterious mutations
305 become effectively neutral. Then, $R_{\beta\gamma}$ is expected to be > 1 when it is calculated based on low
306 frequency variants.

307 The effect of linkage disequilibrium between selective (deleterious or adaptive) and neutral
308 variants should not overly affect the expected estimate of the proportion of adaptive variants, as it
309 would affect both synonymous and nonsynonymous positions in similar proportion. On the
310 contrary, the interaction of variants with opposite selective effects would possibly reduce the effect
311 of selection and would have a significant consequence on the estimation of adaptive fixed variants
312 (Hill and Robertson 1966; Booker and Keightley 2018).

313

314 **Bootstrap analysis**

315 Nonparametric bootstrap analysis was performed to estimate the null distribution of the α statistic
316 for each variability estimator and pig population. In each case, synonymous and nonsynonymous
317 coding positions were randomly chosen with replacement and the α statistic was calculated as in
318 equation 1. This process was repeated 100 times.

319

320 **Simulations**

321 We carried out forward simulations using the software *SLiM* (Haller and Messer 2017) in order to
322 explore the interaction between the different selective effects and demographic factors affecting
323 the evolution of pig populations during domestication. We explored the expected values of
324 nucleotide diversity, divergence, α and $R_{\beta\gamma}$ statistics under 63 different scenarios. For each
325 scenario, we simulated three populations corresponding to wild, domestic and an outgroup species.
326 We first simulated nine different scenarios that were classified into three main groups: i) standard
327 neutral model (SNM); ii) a model with negative selection (NS) and iii) a model with positive
328 selection (PS). For the models with selection, we let that selection operate from the ancestral
329 species to the present time. Each group of scenarios (SNM, NS and PS) was simulated with a
330 constant effective population size for the three populations or with a reduction or an expansion of

331 the effective population size in the branch leading to domestic pigs. A second group of simulations
332 was performed under more complex scenarios. In those simulations, we incorporated the combined
333 effect of negative and positive selective effects (using gamma and exponential distributions for the
334 selective coefficients, respectively) plus demographic effects such as expansion and reduction of
335 the effective population size in the domestic simulated populations and with or without migration
336 from the wild into the domestic populations (in total 54 complex simulated scenarios). Figure S1
337 shows a general scheme for the simulated populations and Tables S3A-B show the parameter
338 values used in these simulations. The obtained results were analyzed using *mstatspop* software
339 (see above).

340

341 **Approximate Bayesian computation (ABC) analysis**

342 We used the ratio of the estimates of nucleotide variability (θ_n/θ_s) per nucleotide for
343 nonsynonymous versus synonymous positions (Fu&Li, Watterson, Tajima and Fay&Wu) and of
344 divergence (Kn/Ks) as statistics to infer the distribution of fitness effects (DFE) in coding regions.
345 We compared four evolutionary models that differ in the shape of the DFE using the algorithm
346 proposed by Tataru et al. (2017), which are the following: (i) model A: a model with a deleterious
347 gamma DFE with the mean and the shape of the gamma distribution as model parameters, (ii)
348 model C: a model with a gamma distribution of deleterious variants with two parameters (shape
349 and mean) and an exponential distribution of beneficial variants with one parameter (mean), and
350 the additional parameter of the proportion of beneficial versus deleterious variants, (iii) model DN:
351 a model with a discrete distribution of a priori values of negative selective coefficients with the
352 proportion of negatively selected mutations for each of the negative selective coefficients as
353 parameters. and (iii) model D: a model with a discrete distribution of a priori values of possible
354 selective coefficients (positive and negative) with the proportion of positively and negatively
355 selected mutations for each selected coefficients as parameters. Some of the additional parameters,
356 such as demographic or linkage effects, were considered as nuisances. Nuisance parameters mimic
357 the demographic effects and other parameters such as linkage effect by using the difference
358 between the observations for the neutral dataset (i.e., synonymous sites) and the expected under
359 the neutral model. Others, such as errors in the polarity of unfolded mutations, were fixed.

360 Table S4 shows the parameters of each model and the prior distributions used in the analysis. We
361 used *polyDFEv2* (Tataru et al 2019) to obtain the expected unfolded site-frequency spectrum
362 (SFS). The code of *polyDFEv2* was slightly modified in order to print the SFS and the parameters
363 for a large number of conditions, which are needed to perform the ABC analysis using summary
364 statistics. For each model, one million iterations were run using different parameter conditions and
365 the resulting SFS for each condition were kept to later calculate the ratios of variability, divergence
366 and the α statistic. The ABC analysis was performed using the R library *abc* (Csillery et al. 2012).
367 We performed a cross validation analysis to evaluate the ability of the approach to distinguish
368 between models using the *cv4postpr()* function, as suggested in the *abc* library documentation.
369 The confusion matrix indicated that these three models were quite distinguishable with a
370 probability of true classification from model A versus C/DN/D of 0.69, from model C versus
371 A/DN/D of 0.65, from model DN versus A/C/D of 0.83 and from model D versus A/C/DN of 0.80,
372 using a tolerance value of 0.05 (Table S5). Posterior probabilities of each model given the observed
373 data (i.e., the probability assigned to each model relative to the other models of the analysis), were
374 obtained using the *postpr()* function and considering a multinomial logistic and a rejection
375 approach. Additionally, a goodness of fit analysis, which evaluates whether the prior distribution
376 for model parameters are realistic, was also performed. The best model was selected based on
377 posterior probabilities. Once the best model was chosen, the ability to infer the parameters of the
378 model was assessed using the *cv4abc()* function. Prediction errors for the parameter inference of
379 each model are shown in Table S6 and Figure S2. The parameters of the best model were inferred
380 with the *abc()* function using a local linear regression and a rejection approach. Posterior predictive
381 simulations were performed using the α statistic to determine whether the simulated data generated
382 from the estimated parameter of our best model resembled the observed data (1000 replicates).
383 Finally, the α values can be simply estimated using equation 10 from Tataru et al. (2017), as the
384 proportion of positive selective coefficients (s) values in the case of the discrete distribution.

385

386 **Gene context and network topology analysis**

387 We downloaded the complete list of pathways and genes of *S. scrofa* from KEGG v.20170213
388 (<http://www.genome.jp/kegg/>, Kanehisa et al. 2008). The list contained 471 pathways and 5,480
389 genes. The median and mean number of genes per pathway was 26 and 43, respectively, and ranged

390 from 1 to 949. We filtered the pathways according to their size, removing pathways with less than
391 10 and more than 150 genes in order to discard pathways that were not informative or too generic
392 and complex. The final list contained 171 pathways and 3,449 genes.

393 To analyze the selection pressure of each gene according to its position in the pathway, we obtained
394 different topological parameters. For that, we first downloaded the XML file of each pathway from
395 KEGG v.20170213. These files were analyzed with the *iGraph* R package (Csardi G. and Nepusz
396 T. 2006) to obtain the topological descriptors of each gene in each pathway. For each gene, three
397 different measures were computed: *betweenness* (number of shortest paths going through a vertex),
398 *in-degree* (number of in-going edges) and *out-degree* (number of out-going edges). These
399 parameters are measures of the importance of a gene within a pathway: *betweenness* is a centrality
400 feature, *in-degree* suggests the facility of a protein to be regulated and *out-degree* reflects the
401 regulatory role of a protein. We tested whether negatively and positively selected genes differed
402 in any of these statistics using a nonparametric Wilcoxon rank test, due to the extreme leptokurtic
403 distributions involved.

404

405 **Genomic context patterns**

406 We have additionally tested whether there is a significant correlation between α and
407 recombination, gene density, missing rate, %GC and CpG islands across genomes.

408

409 **Testing the differences in the estimates of α using whole-genome data versus the mean of** 410 **gene estimates.**

411 We have studied the behaviour of the α statistic when it is estimated considering a single large
412 dataset (*i.e.*, genome) or when it is estimated using the mean of many subsets (*i.e.*, genes). To do
413 that, we made an R script (`check_ratios_vs_meanratios.R`) in which we simulated a hypothetical
414 number of polymorphisms and substitutions per gene, following a Poisson distribution (we
415 considered $\sim 10x$ more substitutions than polymorphisms, $2x$ more nonsynonymous positions than
416 synonymous and $10x$ more functional constraint at nonsynonymous versus synonymous). We
417 estimated α per window and per total. The distribution of α per gene can be strongly skewed to

418 negative values when the windows become smaller, thus dragging the mean to negative values as
419 well.

420

421 All the scripts used are available at Zenodo database
422 (<https://zenodo.org/record/6124306#.YlcVSy8RqLc>).

423

424

425 **RESULTS**

426 **Predominance of shared variants and global similar selective effects of mutations in**
427 **genomic sequences of pig populations**

428 We found a total of 6,684,142 SNPs in autosomes, with 149,440 SNPs located in coding regions.
429 12.5% of the SNPs in the coding regions are shared among the three populations, 32.2% are shared
430 between at least two populations, 31.2% are exclusive to Large White (LW), 2.2% are exclusive
431 to Iberian (IB) and 34.4% are exclusive to Wild boar (WB) (Table 1 and Table S7). The proportion
432 of exclusive SNPs in each population is in accordance with its specific demographic history
433 (Esteve-Codina et al. 2013, Bosse, Megens, Madsen, et al. 2014). Based on the PCA analysis and
434 using the total number of SNPs, we found that the individuals of each breed cluster together and
435 are well separated from other breeds (Figure S3A). The results from the ADMIXTURE analysis
436 (Figure S3B) suggest that, $K=2$ is the most likely number of populations, where WB and IB are
437 considered a single population. Under a $K=2$ scenario, only two LW and one WB individual show
438 a significant percentage of admixture among groups. Nevertheless, for larger values of K , new
439 groups emerge, being the IB one of these separated groups (Figure S3B). However, additional
440 subgroups within WB and LW phenotypes appear and disappear when increasing the K value,
441 making those subgroups apparently unreliable. Therefore, we decided to analyze separately the
442 three breeds, LW, IB and WB, following the main patterns of population structure (Figure S3A)
443 and the phenotypic features of the animals, which essentially separate domestic (commercial and
444 local breed, separately) from wild animals.

445

446

447 **Table 1.** Number of synonymous and nonsynonymous SNPs according to its allelic status in each pig population. A:
 448 Ancestral allele, F: Fixed allele, P: Polymorphic allele. IB: Iberian; LW: Large White; WB: Wild boar. SNPs that are
 449 missing in any of the populations are not considered.

| IB | LW | WB | Synonymous | Non-synonymous |
|-----------|-----------|-----------|-------------------|-----------------------|
| F | F | F | 20297 | 9342 |
| P | P | P | 11712 | 7597 |
| A | A | F | 0 | 0 |
| A | F | A | 0 | 0 |
| F | A | A | 3 | 5 |
| A | A | P | 30314 | 20988 |
| A | P | A | 26027 | 15035 |
| P | A | A | 1833 | 1588 |
| A | F | F | 0 | 0 |
| F | A | F | 1 | 0 |
| F | F | A | 1 | 0 |
| A | P | P | 10128 | 7930 |
| P | A | P | 1676 | 1254 |
| P | P | A | 700 | 363 |
| A | F | P | 11 | 1 |
| A | P | F | 0 | 2 |

| P | A | F | 0 | 0 |
| F | P | A | 8 | 4 |
| P | F | A | 1 | 1 |
| F | P | P | 4924 | 2378 |
| P | F | P | 242 | 139 |
| P | P | F | 81 | 52 |
| F | F | P | 1140 | 489 |
| F | P | F | 4911 | 2073 |
| P | F | F | 38 | 22 |
| | | | 114078 | 69293 |

450

451

452 For each breed, coding positions were classified as polymorphic, fixed (i.e., different allele from
 453 the outgroup) or ancestral allele (i.e., same allele as in the outgroup), with the aim of identifying
 454 those variants that appeared previously or posteriorly to the domestication process (Table 1).

455 Surprisingly, we found very few fixed mutations between populations, indicating that the
456 phenotypic traits of each population are not associated with fixed coding variants. Similarly, we
457 found very few fixed coding variants in domestic (IB or LW) versus wild (WB). There are few
458 variants fixed in the domestic breeds that are polymorphic in the wild population, suggesting that
459 these variants were previously present in wild breeds or, alternatively, were introgressed into WB
460 from domestic breeds. Most of the variants that are exclusive of a single breed are polymorphic,
461 which is in agreement with the recent origin of these variants. We found a large number of fixed
462 variants in the IB that are polymorphic in LW and WB, likely due to a reduction of the effective
463 population size of the IB breed. The ratio of nonsynonymous to synonymous polymorphism was
464 always lower than one and showed similar values for the three populations regardless of the
465 variability estimator used (Table S9). This result suggests that, on average, there are no differential
466 effects of selection between domestic and wild populations, although this might not be the case
467 when individual genes are considered.

468

469 **Low codon bias at whole-genome scale**

470 We estimated the level of codon bias at genome scale using MCU and N_{cw} statistics to control for
471 the possible effect of selection on synonymous positions. Non-neutral synonymous mutations can
472 have a large impact on the inference of the proportion of beneficial selection, and on the estimation
473 of the Distribution of Fitness Effects (DFE). Indeed, the effect of bias in codon usage causes an
474 overestimation of the beneficial proportion of variants that become fixed by increasing the ratio of
475 synonymous polymorphisms versus synonymous fixations (Akashi, 1995, Matsumoto et al. 2016).
476 For this species, we observed a low and large values of MCU and N_{cw} , respectively, indicating low
477 levels of codon bias at genome scale (mean MCU=0.485, Figure S5). However, it should be
478 mentioned that positive selection could be acting on synonymous positions of some specific genes.
479 We therefore have assessed whether there was a correlation between MCU and a , considering all
480 coding regions or only coding regions showing positive a values. We observed no correlation
481 between MCU and a values when considering only genes with positive a values (Figure S5) and
482 slightly negative correlation when considering all genes regarding their respective a values (data
483 not shown).

484

485 **Limited influence of genomic context and the network topology on selective patterns**

486 The heterogeneity in the recombination rate, the gene density, the %GC and the distribution of
487 CpG islands across the genome can affect the local levels of variability. A previous study on the
488 IB breed detected a strong correlation between recombination and variability, although no
489 correlation was observed between variability and gene density or GC content (Esteve-Codina et
490 al. 2013). However, the effect of these factors on the estimation of the proportion of adaptive
491 nonsynonymous mutations (α) has not been previously studied. When we assess whether there is
492 a correlation between the estimated α and the above-mentioned factors, we found that there is no
493 correlation between the estimated α and recombination, gene density, %GC and CpG in any of the
494 three breeds (P -values > 0.01).

495
496 Next, we investigated the effect of gene network topology on the selective patterns. It has been
497 claimed that topology limits the ‘evolvability’ of genes and that highly connected genes are more
498 constrained and, consequently, less likely to be targets of positive selection. We compared the
499 network topology features (*betweenness*, *out-degree* and *in-degree*) of genes within pathways
500 regarding the estimates of α , grouping genes with positive versus negative α values. We found that
501 genes with negative α values show significant large values of the *betweenness* statistic in the three
502 pig breeds compared to genes with positive α values (P -value < 0.01 ; Figure S4). LW and WB
503 showed significant values (P -values < 0.01) of the *in-degree* statistic for genes with negative α
504 values compared to genes with positive α values. However, we did not observe significant
505 differences in the *out-degree* values between genes with negative and positive α values in any of
506 the three breeds (Figure S4). These results suggest that, in the three breeds, genes that are more
507 central in a pathway are more evolutionary constrained compared to peripheral genes. In addition,
508 in LW and WB, the genes that are more constrained tended to have a higher number of upstream
509 genes that regulated them, which is also in agreement with the central position of these genes in
510 the pathway. We did not observe significant differences in *in-degree* statistic in the IB breed
511 between genes with negative and positive α values, likely because of a relaxation of functional
512 constraints as a consequence of the reduction of its effective population size.

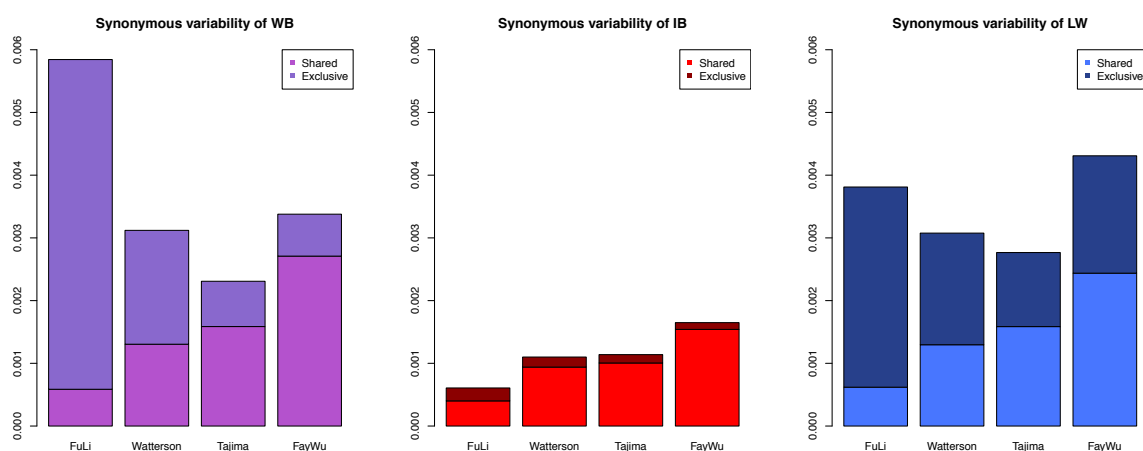

513

514 **Levels of nucleotide variation at protein coding regions are compatible with the history of**
515 **the surveyed pig populations and with the presence of positive selection**

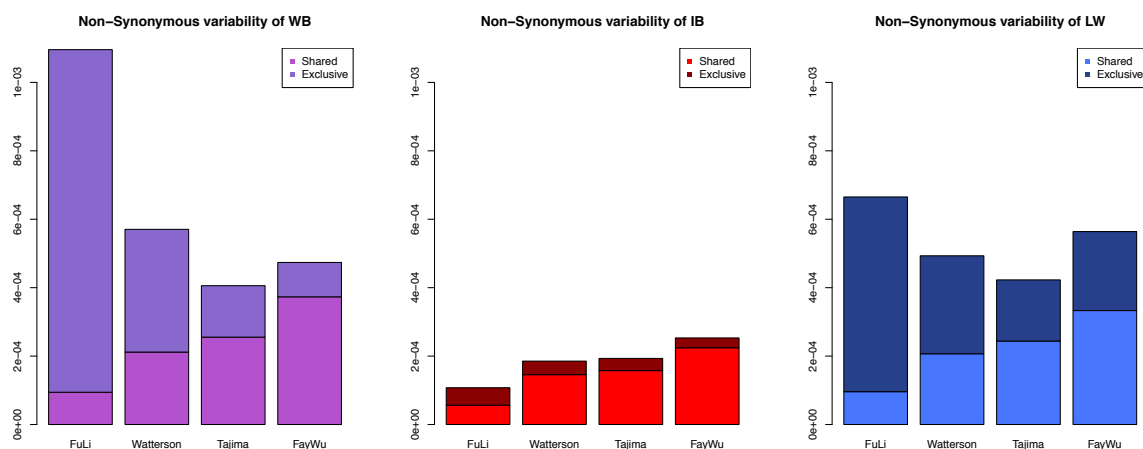

516 To assess the selective effect of domestication, we first studied the pattern of variation at
517 synonymous and nonsynonymous positions using four estimators of variability that differentially
518 weight the SNP frequencies (See Material and Methods). Ideally, it would be more informative to
519 analyze the whole genome Site Frequency Spectrum (SFS). Unfortunately, the relatively high
520 number of positions with missing data discourages their use. A possible alternative would be to
521 obtain the SFS from a reduced number of samples, and therefore use only a partial number of SNPs
522 for subsequent analysis. However, by using this alternative we can either lose power or introduce
523 some sort of bias, hence, we preferred to analyze the whole set of SNPs using those estimates of
524 variability based on different frequencies of the spectrum that account for missing data.
525 Nevertheless, in order to clarify the patterns of the SFS for these populations, we estimated the
526 SFS for a subset of SNPs (around 25-30% of the available coding variants, depending on the breed)
527 for a projection of variants on 38 haploid samples in both LW, WB and on 10 haploid samples in
528 IB (Figure S6). The SFS profile for both synonymous and nonsynonymous showed a rapid
529 decrease in the number of variants from lower to higher frequencies. We observed a slight increase
530 in the number of polymorphisms at the highest frequencies at both synonymous and
531 nonsynonymous sites and no apparent signals of admixture (i.e., no sudden peaks at specific ranges
532 of frequencies). Estimates of whole-genome variability levels per nucleotide using different
533 estimators are shown in Figure 1 and detailed in Table S8. We have considered the synonymous
534 positions as neutral reference since no strong bias in codon usage has been detected (Figure S5).
535 We expect that, under the Standard Neutral Model (SNM), the values for the different estimates
536 of variability should be similar whereas differences among them may indicate demographic and/or
537 selective effects. We observed that i) the levels of variability are different for each estimator within
538 breeds and ii) the levels of variability are different for the same estimator for different breeds.
539 However, for each breed, we observed a similar ratio of nonsynonymous to synonymous
540 polymorphisms regardless of the used estimator, suggesting that demographic effects are
541 responsible for the differences in the levels of variability (Figure 1). The less variable population
542 is the IB breed, which shows far fewer singletons compared to WB and LW, probably as a
543 consequence of the known reduction of its population size. Note that in all the three populations,
544 high-frequency variants are proportionally more abundant than those at intermediate frequencies,

545 which would be compatible with the accepted demographic history of the surveyed populations
 546 (i.e., introgression in LW, bottleneck in IB and some population reduction and introgression in
 547 WB) but also with the presence of pervasive positive selection in all three populations.

A

B

548
 549 **Figure 1.** Estimates of the levels of variation at synonymous (A) and nonsynonymous (B) sites for each variability
 550 estimator and pig population and where variants were classified as shared and exclusive variants. WB; Wild boar;
 551 IB, Iberian; LW, Large White.

552

553 **α 's values and $R_{\beta\gamma}$ ratios based on all SNPs might reflect a differential effect of selection**
554 **due to domestication**

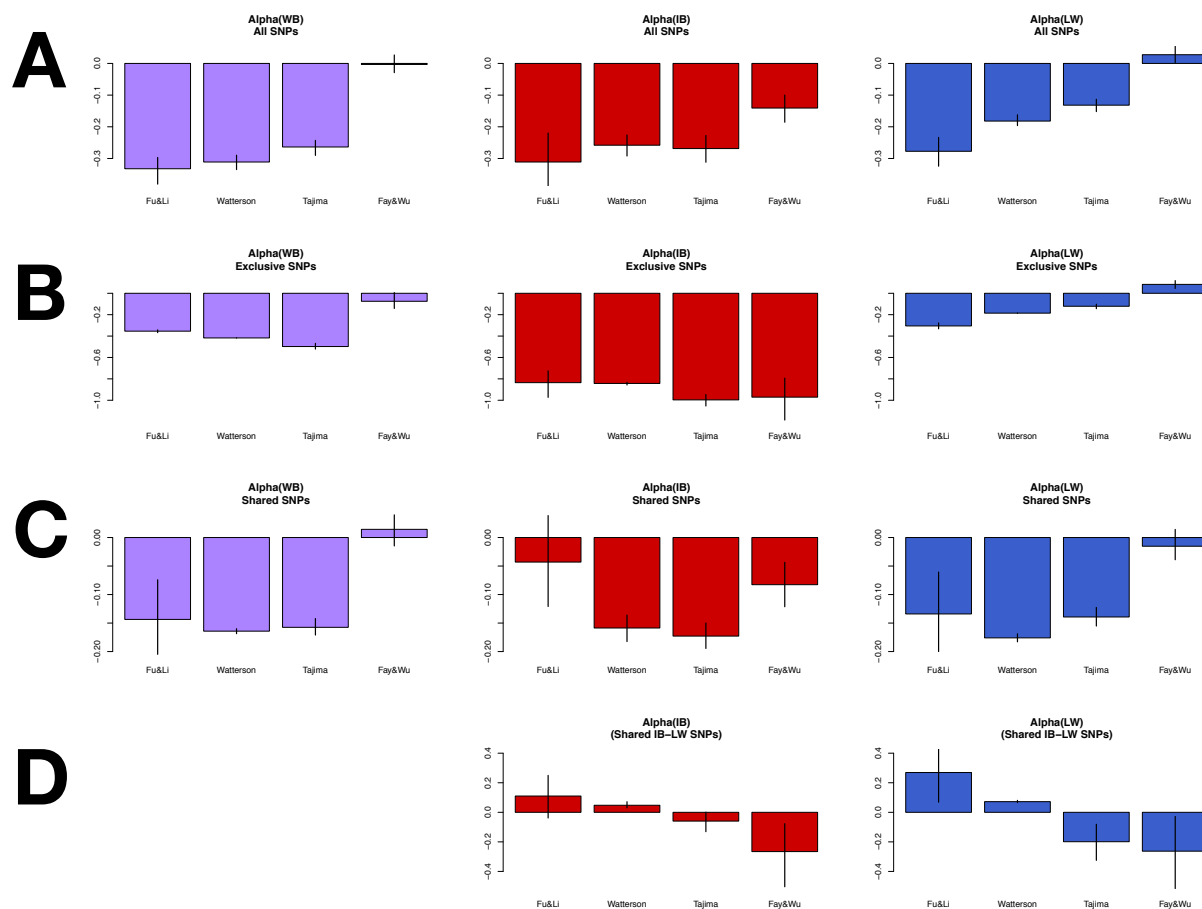

555 The differential effect of selection in the domestic and wild populations can be studied by
556 comparing their respective α values. Figure 2A and Table S9 show the genome-wide α values
557 calculated using the four variability estimators for each population. As expected, the α values are
558 negative when α is calculated using the estimate of variability based on low-frequency variants
559 ($\alpha_{Fu\&Li}$), probably reflecting the relatively high proportion of deleterious versus neutral mutations
560 that are segregating at low frequencies. We observed a similar value of $\alpha_{Fu\&Li}$ in all populations,
561 suggesting a similar proportion of segregating deleterious mutations, irrespective of the
562 domestication process or other demographic events (Figure 2A). Moreover, we observed milder
563 negative values of α , or even positive for LW when α is calculated based on variants at high
564 frequencies (Figure 2A), according to expectations, which point to a progressive elimination of
565 deleterious mutations as we move towards higher frequencies. Nevertheless, the pattern of α (i.e.,
566 the comparative α value calculated using the four different variability estimators within each
567 population) is very different in each population. WB and LW show positive or null α values when
568 it is calculated based on high frequencies (Table S9). Instead, IB show very low negative α values
569 for all estimators of variability. We found a compatible pattern when using the reduced subset of
570 SNPs for the SFS estimation (Figure S6-A), where it can be observed that the estimates of α in all
571 three populations are very similar among them ($\alpha \sim -0.05$), although their confidence intervals are
572 quite wide.

573

574 The differences in the ratio of synonymous to nonsynonymous variability between the two
575 different breeds is summarized by the $R_{\beta\gamma}$ ratio (Figure 3). We observed that the largest deviations
576 from $R_{\beta\gamma} = 1$ are observed when the ratio was calculated based on high-frequency variants
577 ($\alpha_{Fay\&Wu}$). Although the ratio of the two populations is difficult to interpret because of their
578 different underlying demographic histories, some trends can be observed. WB shows an excess of
579 nonsynonymous variants segregating at intermediate frequencies (WB-IB, WB-LW), which might
580 be explained by a past bottleneck that increased deleterious mutations at intermediate frequencies.
581 In addition, the $R_{\beta\gamma}$ ratio in IB-LW shows an incremental pattern of this ratio from low to high

582 frequencies, which is compatible with an increase of nonsynonymous beneficial variants on their
 583 way to fixation in LW.

584

585

586 **Figure 2.** Estimates of α for each pig population based on different variability estimators. Total variants (A), exclusive
 587 variants (B), shared variants (C) and shared variants between IB and LW (D). Bootstrap intervals at 95% are indicated
 588 by a line at each bar. WB; Wild boar; IB, Iberian; LW, Large White.

589

590 **α 's and $R_{\beta\gamma}$ ratios based on exclusive and shared polymorphisms might reflect changes in**
 591 **selective patterns before and after domestication**

592 We observed a high ratio of nonsynonymous to synonymous singletons ($\alpha_{Fu\&Li}$, Figure 2B) when
 593 the analysis was performed based on exclusive polymorphisms, suggesting that they have
 594 deleterious effects in all populations. Nevertheless, the values of α calculated based on

595 intermediate frequency variants (α_{Tajima}) in the WB and IB populations are lower than to those
596 based on low-frequency variants, which point to a change in the selective pressure, maintaining
597 nonsynonymous variants at relatively high frequencies. Nevertheless, the $\alpha_{Fay\&Wu}$ values (-0.075,
598 -0.971 and 0.083 for WB, IB and LW, respectively, Table S9) show a similar trend in relation to
599 that based of Total SNPs, that is, close to 0 or positive for WB and LW, but strongly negative for
600 IB. Concordant estimates are observed in the analysis of the SFS based on a reduced number of
601 SNPs (0.155, -0.913 and 0.277 for WB, IB and LW, respectively, Figure 6B), with the difference
602 that a clear positive and not 0 α values is observed in WB. The $R_{\beta\gamma}$ statistic shows the same
603 pattern as that calculated using all SNPs but with all over one (Figure 3). That indicates that WB
604 has a higher proportion of nonsynonymous polymorphisms compared to IB, in contrast to what is
605 observed when the analysis is performed based on all SNPs. This would suggest a recent change
606 in the constraint of nonsynonymous positions likely at IB breed, as this ratio in IB-LW is also
607 affected. This is also in agreement with the low α value in IB breed at exclusive variants regarding
608 to Total SNPs.

609
610 On the other hand, the α values based on shared variants are in general more moderate (closer to
611 zero) than those based on exclusive variants (Figure 2C), likely because shared nonsynonymous
612 polymorphisms are older and hence, expected to be more functionally constrained than the
613 exclusive ones. Additionally, the values of α based on singletons ($\alpha_{Fu\&Li}$) are less negative than
614 those based on intermediate-frequency variants. The α estimates based on shared variants in the
615 analysis of the reduced subset of SNPs are very similar to Total SNPs and very close to zero (Figure
616 6C). The $R_{\beta\gamma}$ statistic for shared variants shows similar patterns than those observed for all
617 variants but with values much closer to 1, indicating a small or moderate selective effect on the
618 shared variants compared to all variants (Figure 3).

619
620 When we calculated the α values from shared variants only between the two domestic breeds, we
621 found an inverse pattern regarding to that calculated from all SNPs in each population, with high
622 positive values of α based on low frequencies and very negative values when α is calculated based
623 on high-frequency variants (Figure 2D). This could be due to i) the active elimination of new
624 nonsynonymous variants to preserve differences among domestic breeds ($\alpha_{Fu\&Li}$) and ii) the

625 presence of nonsynonymous variants targeted by the process of domestication that shifts them
626 toward high frequencies ($\alpha_{\text{Fay\&wu}}$). Nevertheless, we cannot discard that this excess of
627 nonsynonymous variants at high frequencies and the lack of nonsynonymous singletons at low
628 frequency could be due to a more complex and not previously explored demographic scenario.
629

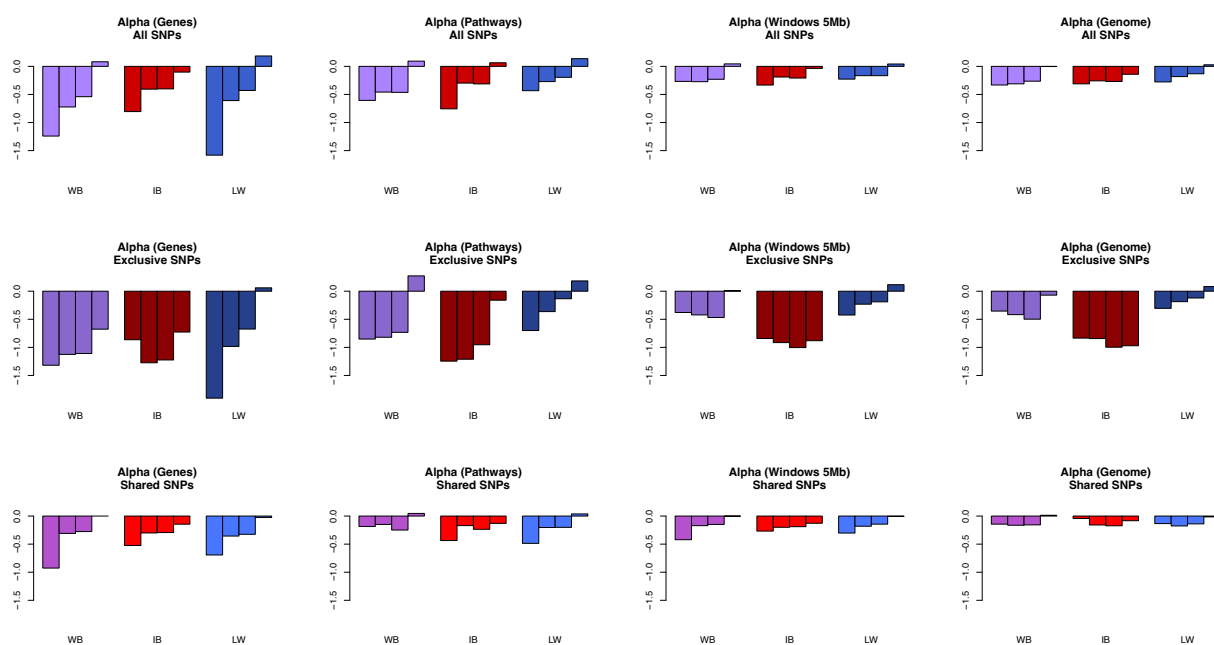

630
631 **Figure 3.** Estimates of $R_{\beta\gamma}$ for all (left), exclusive (centre) and shared (right) variants. WB; Wild boar; IB, Iberian;
632 LW, Large White.

633
634 **Values of α are dependent of the molecular scale but the patterns of the estimated α 's are**
635 **similar across the different molecular scales**

636 In addition to the genome-wide analysis, α was calculated using three additional molecular scale
637 levels: i) gene level, ii) genes within windows of 5 Mb, and iii) genes within the same pathway.
638 Figure 4 shows the median of the distributions of the α values for each scale level. When the
639 analysis was performed based on all SNPs, the pattern of α values estimated at the genome-wide
640 level are concordant with those estimated at the gene level, genes within windows and genes within
641 pathways for each breed. However, differences in the value of α within each breed are notorious
642 depending on the scale level examined. The median estimates of α are generally lower at the gene
643 scale level and most of them are very negative, while at the genome-wide scale, the α values are
644 closer to zero. However, the distribution of α values can have a large variance at the gene scale
645 since few variants are used for its estimation. We identified the regions and pathways that showed
646 extreme α values (Table S10 and S11). We found a large number of genes showing $\alpha = 1$ (highest
647 value) because the number of polymorphic nonsynonymous variants per gene was zero. We also
648 found a moderately high correlation of α values between breeds ($\rho \sim 0.7$, Pearson correlation

649 when considering pathways) suggesting that in general, these breeds are under similar selective
650 effects. When considering shared and exclusive variants, we generally observed the same pattern,
651 from genes to whole-genome, that is, larger α values at the gene level and closer to zero α values
652 at the larger scale. The differences in α values could be explained because of the distribution of
653 this ratio statistic (*i.e.*, skewed distribution to negative values) and the uneven distribution of the
654 functional variants, in which the mean can be displaced to more negative values (see Materials and
655 Methods).

656

657
658 **Figure 4.** Estimates of the median values of α based on different variability estimators and for each pig population at
659 different molecular scales and for all, exclusive and shared variants. Within each population, the order of different α 's
660 is: Fu&Li, Watterson, Tajima and Fay&Wu. WB; wild boar; IB, Iberian; LW, Large White.

661
662 **Simulated data under different scenarios that include the joint effect of demography and**
663 **selective events were more concordant to the observed data**

664 We used computer simulations to study how the different demographic and selective events
665 occurred during domestication process shaped nucleotide variation present in these populations.
666 We simulated populations mimicking the process of domestication using *SLiM* software (Haller
667 and Messer 2017), coupled with several demographic events, including changes of the population

668 size and/or migration. We analyzed the genome-wide patterns of α and the $R_{\beta\gamma}$ statistic produced
669 by 63 simulated scenarios that included different demographic events and selective forces acting
670 separately (simple scenarios) or jointly (complex scenarios). The results of the simulation study
671 are summarized in Figures S7-S48. The observed patterns of α based on all variants in the surveyed
672 populations are not compatible with simple scenarios that only consider demographic or positive
673 selection forces (Figure S7). Rather, α patterns from simulated data (irrespective of the magnitude
674 of α) fit a scenario with a predominant effect of negative selection (Figure S7). However, the $R_{\beta\gamma}$
675 statistic do not fit any of the simulated simple scenarios (Figure S8). When more complex scenarios
676 were considered (i.e., including a bottleneck, positive/negative selection and/or migration, Figures
677 S9-S14), the general α patterns generated by those scenarios that include both negative and positive
678 selection resembled those observed in WB and LW (with negative α 's at low frequency values to
679 slightly positive α values at high frequency). The scenarios that also include some migration events
680 are the ones that showed more concordance for these two breeds (Figures S12, S14). On the other
681 hand, the IB population is more compatible with a scenario without positive selection and with a
682 recent population size reduction (Figure S13). The trends in the $R_{\beta\gamma}$ statistic are, in broad strokes,
683 concordant with the conclusions extracted from the comparison between the observed and
684 simulated patterns of α (Figures S15-S20).

685
686 The observed patterns of α values based on exclusive variants are similar to those based on total
687 variants but only for the LW population (Figure S21). These patterns cannot be fully explained by
688 any of the complex simulated scenarios that are concordant when considering all variants, although
689 surprisingly, they would be more compatible with those including a population size reduction
690 (Figures S24-S28). The observed $R_{\beta\gamma}$'s are compatible with the scenarios that combine both types
691 of selection and a population size reduction (WB-IB) or with scenarios that include migration
692 (WB-LW; Figures S29-S34). Finally, the observed patterns of α and $R_{\beta\gamma}$ statistics calculated from
693 shared variants are also compatible with scenarios which includes both types of selection (Figures
694 S35-S48), and being quite compatible with those including expansion demographic events.
695 Overall, the simulations data showed that complex scenarios, including demography, migration,
696 and positive and negative selection, may be necessary to explain the observed data.

697

698

699 **Table 2.** Posterior Probabilities for each ABC model (multinomial logistic method with tolerance 0.01)
700 and for each pig population for Total variants, Exclusive variants, and Shared variants.

Posterior probabilities for model comparison (multinomial logistic method)

| TOTAL | modelA | modelC | modelDN | modelD |
|------------------|---------------|---------------|----------------|---------------|
| WB | 0.000 | 0.039 | 0.623 | 0.338 |
| IB | 0.000 | 0.031 | 0.968 | 0.001 |
| LW | 0.000 | 0.195 | 0.526 | 0.279 |
| EXCLUSIVE | modelA | modelC | modelDN | modelD |
| WB | 0.007 | 0.011 | 0.512 | 0.470 |
| IB | 0.004 | 0.001 | 0.995 | 0.000 |
| LW | 0.001 | 0.111 | 0.113 | 0.775 |
| SHARED | modelA | modelC | modelDN | modelD |

| IB | 0.000 | 0.413 | 0.576 | 0.011 |
| LW | 0.001 | 0.447 | 0.462 | 0.090 |

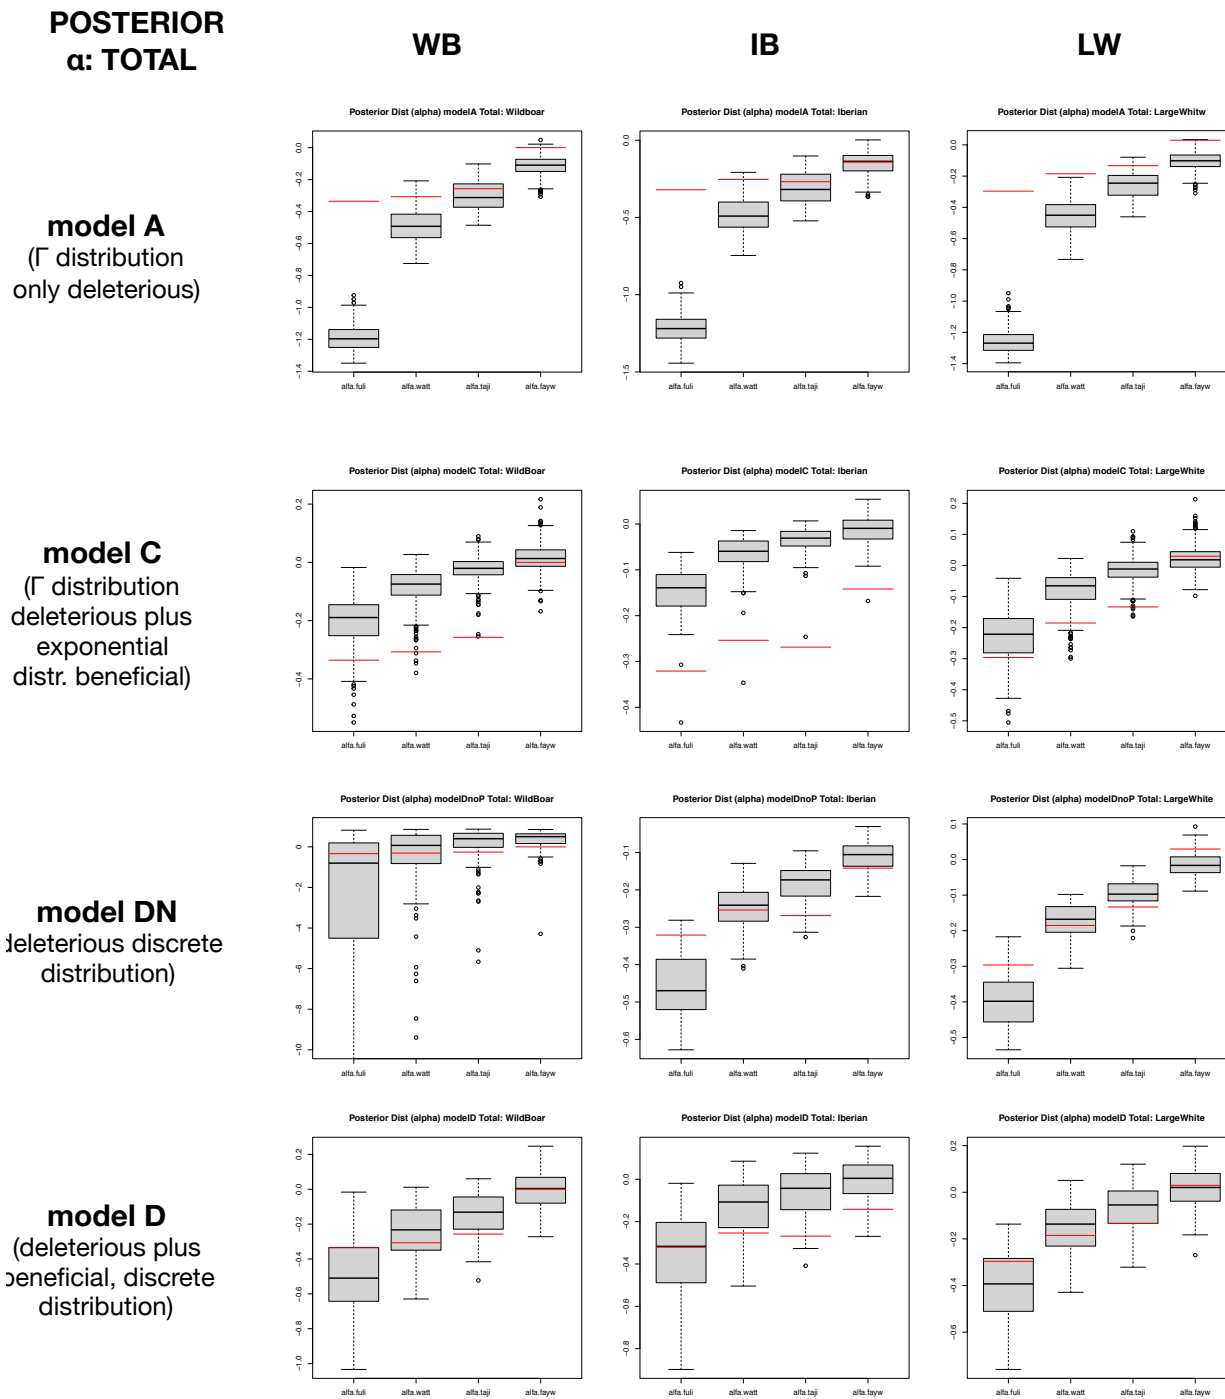

701

702 **Models that assume a discrete distribution of beneficial and deleterious mutations would fit**
703 **better the observed data**

704 We used an approximate Bayesian computation (ABC) analysis to infer the DFE separately for
705 each population using the ratios of nonsynonymous to synonymous variants (i.e., polymorphism
706 and divergence) obtained from the whole-genome analysis (see Materials and Methods). Four
707 different models implemented in *polyDFE2* software (Tataru et al. 2019) were tested. These
708 models overcome the inference of the demographic parameters (and others such as linkage effects)
709 by the inclusion of nuisance parameters (see Material and Methods). The four models were: model
710 A, which assumes a gamma distribution of deleterious mutations; model C, which assumes a
711 gamma distribution for deleterious mutations and an exponential distribution for beneficial
712 mutations; model DN, that assumes a discrete distribution of only deleterious and neutral
713 mutations, and model D, that assumes a discrete distribution of deleterious, neutral and beneficial,
714 mutations. Goodness of fit (GoF) analysis revealed that the simulated data under the different
715 models fits differentially to the observed data, although the used range of parameters for priors are
716 compatible with the observed data for all the four models (Table S12). Posterior probabilities
717 showed that the DN is the most likely model for all three populations when using total number of

718 variants (Table 2). The posterior probability for this model is especially high for the IB breed
719 (0.97). Nevertheless, note that the model D is just below the DN model by less than half of the
720 probability in the case of WB and LW. Finally, the posterior predictive analysis indicated that the
721 observed α values for the three populations are within the range determined by the minimum and
722 maximum simulated α values (i.e., $Q1-1.5*IQR$, $Q3+1.5*IQR$, respectively, being IQR the
723 Interquartile Range $Q3-Q1$) under both models DN and D, although not always inside the Q1 and
724 Q3 quantiles (Figure 5). The mean parameters of the DFE inferred for each population are shown
725 in Table 3 (see also Table S13). The obtained results indicated that the DFE is quite similar among
726 all three populations, which is not entirely surprising because they share a long-term history.
727 According to model DN, and despite there is a lot of uncertainty in the inferred estimates (Table
728 S13), the obtained results show that the DFE contains a large fraction of very deleterious variants,
729 with approximately 75% of the variants being strongly deleterious ($S = -2000$), and with
730 approximately 12% of the variants being neutral or slightly deleterious (approx. 4%). The model
731 D infers a higher proportion of weak deleterious mutations compared to the neutral ones, although
732 the sum of both is similar to model DN. Finally, the inferred contribution of positive selection is
733 relatively low (around 0.7-1.1%).

734

735

736 **Figure 5.** Posterior distributions of the α values for total variants based on different variability estimators (Fu&Li,
737 Watterson, Tajima and Fay&Wu). Box plots indicate simulated distributions of α values. Red lines indicate observed
738 α values.

739

740 **The differential patterns of DFE based on exclusive versus shared variants may indicate**
741 **selective differences after the split of the populations**

742 We are aware that the inference of the SFS is going to be highly distorted by choosing only a
743 subsection of the variants (e.g., exclusive variants are mostly very recent and have no time to reach
744 high frequencies and shared variants show no or few singletons per populations). However, the
745 nuisance parameters incorporated in polyDFE should account for this effect (Tataru et al. 2017).
746 The classification of polymorphisms in exclusive or shared are dependent of the relationship
747 between two populations, and are a priori not related to the selective effect of these polymorphisms
748 across their frequencies, although shared (mostly older) and exclusive (mostly recent) variants are
749 chronologically related to the selection of variants. Then, we considered that the inference of DFE
750 from exclusive and shared polymorphisms can give some clues about recent and past events related
751 to the domestication processes. The models with higher posterior probabilities in the case of WB
752 and IB breeds based on exclusive variants are the same than those for total variants (Table 2).
753 However, for LW and based on exclusive variants, the model D has higher posterior probabilities,
754 in contrast to what was obtained based on total variants (Table 2). The posterior predictive
755 simulations showed that the models DN and D yielded similar estimated a values to those from
756 the observed data, with the IB breed exhibiting the posterior distributions of a values more distant
757 to the observed data (Figure 6). The estimates of the parameters of the models indicate that, for all
758 populations, the exclusive segregating variants exhibit less strongly deleterious effects compared
759 to those based on total and shared variants (Table 3). Indeed, the IB breed shows significantly
760 lower proportions of strong deleterious mutations, according to its assumed recent population
761 decline. As in the analysis based on total variants, posterior predictive analysis based on exclusive
762 variants showed that models DN and D are those generating a values more similar to the observed
763 ones, but in this case, the observed a values for the IB breed were slightly closer to the simulated
764 a 's, compared to those based on total variants (Figure 6). The results obtained based on shared
765 variants also show that the DN is the most likely model for all populations, although the model C
766 shows closer probabilities (Table 2), especially in the case of LW, which might suggest that shared
767 variants may have played a significant role as a substrate for adaptive process. However, posterior
768 predictive distribution of a values for this breed under this model resembled less the observed data
769 compared to those for the most likely models (Figure 7).

788

789 **DISCUSSION**

790 The study of the genetic effects produced by domestication can be challenged for many reasons.
791 First, the current domesticated species have been severely manipulated by humans, which means
792 that most of individuals were not crossed randomly, and consequently, different complex
793 domestication scenarios can be found such as a high degree of structuration, a fast creation of new
794 lineages from highly inbreeding crosses, a forced introgression between far related populations or
795 from close species and a very divergent selective events across time and space, among others (e.g.,
796 Mignon-Grasteau et al. 2005, Ross-Ibarra et al. 2007, Ramos-Onsins et al. 2014, Gaut et al. 2018).
797 Moreover, in animals, the polygenic nature of the domestication traits often precludes identifying
798 their underlying genes since the domestic phenotypes might be probably caused by subtle allele-
799 frequency changes of variants distributed throughout the genome, and hence, very difficult to be
800 detect. In addition, the study of the effects of selection using genome sequences that contain a
801 nonnegligible fraction of missing data, such as those from non-model organisms, is challenging
802 and needs the use of appropriate methods to account for these positions. Statistics that exploit the
803 frequency of the variants while accounting for missing data are particularly appropriate for such
804 analyses (Ferretti, Raineri, and Ramos-Onsins 2012). Despite all this inconvenience, domestic
805 populations are an excellent model to study the effect of strong and recent selection (e.g., Doebley,
806 Gaut and Smith 2006, Groenen 2016).

807

808 One of the main goals of this work is to provide a novel approach that combines the use of different
809 estimators of variability that account for missing data with the asymptotic approach proposed by
810 Messer and Petrov (2013) and Uricchio et al. (2019) in order to take into account some of these
811 issues. This approach is designed to be used as an alternative in case of the estimation of the full
812 SFS is compromised by large amounts of missing data. Although it can be less precise (we used
813 only four statistics to capture the entire trend of α 's across the SFS), it allows analyzing a larger
814 number of positions, helps to reduce the variance (by summarizing the SFS into few statistics) and
815 facilitates the visual interpretation. To illustrate the utility of the proposed approach, we used this
816 methodology to perform an exhaustive comparative study of the observed patterns of functional
817 versus neutral diversity and divergence in domestic pigs and wild boars. In addition, and to delve
818 deeper into the domestication process of this species, we also performed a forward simulation

819 study, including several diverse evolutionary scenarios and the inference of DFE parameters given
820 different selective models. Note that the DFE was inferred using Bayesian calculations (ABC)
821 instead of exact Bayesian or Likelihood methods since despite ABC requires additional steps and
822 validation analysis and is in general less precise, it allows contrasting models and inferring
823 parameters from complex datasets or data containing missing information (Beaumont et al. 2002).
824 Finally, we have also analysed exclusive and shared polymorphisms separately to extract
825 information about the new and the past domestication events of the demographic history of these
826 populations, but also about the role of population admixture.

827

828 **General selection pressures on pigs and the process of domestication**

829 Like us, others have been already performed several analyses to shed light on the process of
830 domestication using the MacDonald and Kreitman extension methods or using other estimates
831 such as variability or divergence at functional or synonymous positions (MacEachern et al. 2009,
832 Kono et al. 2016, Makino et al. 2018). As in Makino et al. (2018), we do not observe an increase
833 in functional diversity in domestic versus wild populations. This may be explained by several
834 recent events occurring in these populations: (i) differences in the recent history our local and
835 commercial domesticated populations (i.e., high inbreeding degree in Iberian local pigs and recent
836 gene flow from Asian pigs into the commercial pigs); (ii) demographic effects in the wild boar
837 population that may have reduced their diversity (Groenen et al 2016) or have increased the
838 confidence intervals of the patterns of α 's (Figures S5-S46); (iii) differential adaptive forces in
839 local (IB) versus commercial pigs (LW), with a recent high selective pressure in this last
840 population.

841 Accordingly, with their recent history, the IB breed shows the lowest levels of synonymous and
842 nonsynonymous variation among the breeds studied. Note that the two domestic breeds analyzed
843 here have very different recent histories: the IB is a local Spanish breed (Guadyrvas) that suffered
844 a strong bottleneck during the 1970s (Esteve-Codina et al. 2013) and with no evidence of
845 introgression whereas the LW breed was admixed with pigs of Asian origin (Bosse, Megens,
846 Madsen, et al. 2014). Therefore, our observations are perfectly compatible with the small effective
847 population size and the close relatedness of the individuals expected for this population. However,
848 for the other two breeds, the obtained results do not seem to conform to what was expected. since

849 we detected very similar levels of variability between LW and WB, even though we expected to
850 find higher levels of variation in the first due to the documented introgression of Asian germplasm
851 into LW (approximately 20–35% of the genome has been estimated to be of Asian origin; Groenen
852 et al. 2012, Bosse et al. 2012, Bosse, Megens, Madsen, et al. 2014, Frantz et al. 2015, Bianco et
853 al. 2015, Ai et al. 2015). Interestingly, the high levels of variability were observed for variants that
854 belonged to different frequency ranges in these two populations: singletons in WB and in high-
855 frequency derived alleles in LW. Although these differences may be mainly due to the effects of
856 gene flow in LW, we cannot discard an important effect of the selective programs applied to this
857 commercial breed.

858

859 **Domestication hallmarks at pig coding regions**

860 Another main goal of this work was finding the hallmarks of positive selection produced as a
861 consequence of the domestication since this process implies a process of positive (human
862 mediated) selection for traits that benefit both humans and the species of interest. The paucity of
863 fixed variants found at coding positions in the three breeds indicates that the observed heritable
864 phenotypic differences among the breeds are either due to: i) very few selective sweeps, ii) positive
865 selection at noncoding functional regions that were not analyzed in here, iii) changes in the
866 frequencies of nonsynonymous variants without being fixed. If the first hypothesis is true, we
867 expect that domestication process should fix the adaptive variants for those genes underlying the
868 phenotypes of interest. However, we found no fixed variants between domestic breeds and wild
869 pigs. Although this might be a consequence of some genetic exchange among populations, we
870 found that the individuals were classified in groups by their location and according to their
871 respective phenotype (Figure S3A), which suggest that the domestication features of the different
872 breeds, even if admixed, are maintained. When we checked the α values for those genes that were
873 previously reported to show signals of positive selection using other approaches (Groenen 2016),
874 we found that these genes show little or no nonsynonymous polymorphisms or fixed variants
875 (Table S14). This absence of variability is typical from regions under selective sweeps, although
876 not necessarily implicating that these genes are the targets of domestication since there are no
877 variants fixed or close to fixation at their coding regions. We only found significant values of α
878 over zero at the gene *KIT* in the IB breed, the genes *IGF2R* and *JMJD1C* in the LW breed and the

879 gene LRRTM3 in the WB population. This low number of genes with positive α values would
880 make the first hypothesis unlikely. The second hypothesis implies that the functional regions
881 implicated in domestication would be out of coding regions (promoters, enhancers, and others.
882 (e.g., Li et al 2018, Rubin et al 2012, Anderson 2012). However, although being a promising
883 hypothesis, we did not analyze those regions because it requires a very accurate analysis of
884 homology and their associated functionality, which is very complicated at the genome level,
885 especially for non-model species with a high proportion of missing data. The third hypothesis
886 suggests that the domesticated phenotype is caused by a moderate change in the frequency of a
887 relatively large number of variants with small selective effects. In this case, depending on the size
888 of the selective effect there would only be changes in the frequencies of the variants without
889 reaching fixation. In the last case, the functional variants involved in domestication should be
890 segregating in the analyzed populations. These positively selected variants segregating at high
891 frequencies, together with the presence of deleterious mutations also segregating at low
892 frequencies, would be reflected as an excess of non-neutral polymorphism compared to divergence
893 (*i.e.*, negative α statistic at high frequencies). Hence, in cases where there is a significant
894 proportion of positive selection variants that have not yet being fixed, we expect to observe a trend
895 in the α slope showing more negative α values at intermediate-high frequencies. However, we did
896 not observe this pattern in any of the three populations examined when the analysis was performed
897 based on all coding positions, although it was observed for α values estimated based on exclusive
898 and shared mutations, which suggest that different types of variants (total, shared and exclusive)
899 could be capturing different aspects of the domestication process (demography versus selection).

900 The estimation of the DFE from the ABC analysis showed that the most likely evolutionary model
901 for all three populations based on total variants was that consisting in a discrete DFE without
902 significant positive selection effect (model DN; Table 2), showing a clear genome-wide effect of
903 the action of purifying selection. We also observed a reduced effect of purifying selection in IB
904 and in less extend in WB when the analysis was performed based on exclusive variants, which
905 suggest a reduction of the population size of these two populations. However, for LW and when
906 the analysis was performed based on exclusive positions, the most likely model was that with a
907 discrete distribution that includes the effect of positive selection (model D; Table 2), which may
908 reflect the increase of new Asian variants which increased in frequency by artificial selection..
909 Nevertheless, the differences between models including or excluding beneficial variants were

910 relatively small, suggesting that, in general, a few proportion of beneficial mutations contributed
911 to the domestication process. In fact, under model D, the estimated global proportion of beneficial
912 mutations (weak and strong) was relatively small and slightly higher when the analysis is based
913 on shared variants (0.1% based on total and exclusive SNPs and 1.4% based on shared SNPs;
914 Table 3) and similar in wild and domestic populations. Nevertheless, this proportion of mutations
915 may be substantial in absolute numbers (*i.e.*, several thousand mutations).

916 Although an excess of nonsynonymous shared variants compared to the synonymous ones can be
917 explained by some demographic scenarios such as bottlenecks, they may also reflect biological
918 constraints at the species level. For instance, the phenotypic variation in a polygenic selective
919 scenario could be caused by subtle changes in the frequencies of many genes (in an infinitesimal
920 scenario) which would result in the observed phenotypic differences among the breeds. On the
921 other hand, exclusive variants may reflect recent and breed-specific selective hallmarks and hence,
922 would be responsible for the observed differences between domesticated and wild breeds. In both
923 cases, shared and exclusive polymorphisms are contributing to the differences in the SFS between
924 functional and non-functional positions. Nevertheless, the differences of the DFE when the
925 analysis was performed based on total or shared variants is very small, suggesting that exclusive
926 variants would be more informative to detect the effects of the change of selective effects.

927 In addition, our simulated domestication scenarios indicate that the effect of positive selection
928 irrespective of being either strong and affecting a small percentage of variants or weak and
929 affecting a large percentage of variants is not reflected as marked changes in the estimated patterns
930 of α . This could be due to the short time since the change in the fitness effects of variants occurred
931 but also by the interaction of positive and negative selection and demographic processes in the
932 case of the complex scenarios, which are the most compatible with the observed data. In fact, the
933 observed α patterns are compatible with the simulated demographic effects (population size
934 reduction in WB and IB and gene flow in LW) but also, as in the ABC analysis results, with the
935 effect of positive selection in LW when the analysis was based on exclusive variants.

936 We are aware that the evolutionary models used here are very simple and contain few parameters
937 and the real observations contain high heterogeneity that could not be fitted to these models. The
938 reasons for this heterogeneity may be technical (e.g., not adequate filtering of raw sequences),
939 conceptual (undetected correlations that distort model assumptions) or biological (too simplistic

940 models to explain the real data). In any case, the model that assumes a discrete distribution of
941 deleterious mutations (model DN) seems to generally explain better the observed data, together
942 with the model D (model DN but including the effect of beneficial selection) in a minor degree
943 and also that exclusive variants seemed to be more informative to detect the changes of the
944 selective effects.

945

946 **Final remarks**

947 The observed patterns of variability are compatible with the presence of deleterious mutations
948 segregating in all three breeds but also with weak signals of positive selection. In addition, when
949 the variants are split into shared and exclusive, we observed patterns that are in line with the
950 simulated data under different demographic scenarios with the joint action of positive and negative
951 selection. We found a clear effect of deleterious mutations at low-frequency variants and a possible
952 mild effect of positive selection at higher frequencies. However, additional analyses contrasting
953 evolutionary models that consider the effects of standing variation, whose effect change under the
954 domestication process, may shed more light and will help to understand the patterns of variation
955 shaped by the domestication process.

956

957 **ACKNOWLEDGMENTS**

958 We acknowledge L. Silió and M. C. Rodríguez for helpful comments on the manuscript. S.E.R.O.
959 is supported by grants AGL2016-78709-R (MEC, Spain) and PID2020-119255GB-I00 (MICINN,
