Abstract

Salmonella enterica subspecies enterica serotype Typhimurium phage type DT104 (DT104) can infect both humans and animals and is often multidrug-resistant (MDR). Previous studies have indicated that, unlike most S. Typhimurium, the overwhelming majority of DT104 strains produce a pertussis-like toxin, ArtAB, via prophage-encoded artAB; however, DT104 that lack artAB have been described on occasion. Here, we identify a MDR DT104 lineage circulating among humans and cattle in the United States, which lacks artAB (i.e., the “U.S. artAB-negative major clade”; n = 42 genomes). Unlike most other bovine- and human-associated DT104 strains from the U.S. (n = 230 total genomes), which harbor artAB on prophage Gifsy-1 (n = 177), members of the U.S. artAB-negative major clade lack Gifsy-1, as well as anti-inflammatory effector gogB. The U.S. artAB-negative major clade was predicted to have lost artAB, Gifsy-1, and gogB circa 1985-1987 (95% highest posterior density interval 1979.0-1992.1), in close temporal proximity to a predicted rapid increase in the U.S. DT104 effective population size (circa 1983-1989). When compared to DT104 genomes from other world regions (n = 752 total genomes), several additional, sporadic artAB, Gifsy-1, and/or gogB loss events among clades encompassing ≤5 genomes were observed. In phenotypic assays that simulate conditions encountered during human and/or bovine digestion, members of the U.S. artAB-negative major clade did not differ from closely related Gifsy-1/artAB/gogB-harboring U.S. DT104 strains (ANOVA raw P > 0.05); thus, future research is needed to elucidate the roles that artAB, gogB, and Gifsy-1 play in DT104 virulence in humans and animals.
Impact Statement

Multi-drug resistant (MDR) *Salmonella enterica* serotype Typhimurium phage type DT104 (DT104) was responsible for a global epidemic among humans and animals throughout the 1990s and continues to circulate worldwide. Previous studies have indicated that the vast majority of DT104 produce a pertussis-like toxin, ArtAB, via prophage-encoded *artAB*. However, here we identify a DT104 lineage circulating among cattle and humans across ≥11 U.S. states, which lacks the ability to produce ArtAB (i.e., the “U.S. *artAB*-negative major clade”). The common ancestor of all U.S. *artAB*-negative major clade members lost the ability to produce ArtAB in close temporal proximity to the global MDR DT104 epidemic; however, the reason for this loss-of-function event within this well-established pathogen remains unclear. The role that ArtAB plays in DT104 virulence remains elusive, and phenotypic assays conducted here indicate that members of the U.S. *artAB*-negative major clade do not have a significant advantage or disadvantage relative to closely related Gifsy-1/*artAB*/gogB-harboring U.S. DT104 strains when exposed to stressors encountered during human and/or bovine digestion *in vitro*. However, ArtAB heterogeneity among DT104 suggest clade-specific selection for or against maintenance of ArtAB. Thus, future studies querying the virulence potential of the U.S. *artAB*-negative major clade are needed.

Data Summary. The authors confirm all supporting data, code and protocols have been provided within the article or through supplementary data files.
INTRODUCTION

Prophages, which are viruses located within the genomes of bacteria, play important roles in the evolution of their microbial hosts [1-4]. In addition to possessing machinery that is antagonistic to host cell survival (e.g., virion production, lysis of host cells), many prophages encode accessory genes, which may provide the host with a selective advantage [1, 3, 5], including stress tolerance, resistance to antimicrobials and phage, biofilm formation, increased virulence, and evasion of the host immune system [1, 2, 4-8]. While they may persist within a lineage through vertical transmission [5, 6, 9], prophages can undergo gain and loss events within a population over time [1, 3]. Furthermore, integrated prophages can be hotspots for horizontal gene transfer (HGT) and genomic recombination, allowing their bacterial hosts to gain, lose, and exchange genetic information [4]. Thus, prophage-mediated HGT may confer novel functions, which allow the bacterial host to survive and compete in its environment, potentially contributing to the emergence of novel epidemic lineages [4, 10].

Salmonella enterica subsp. enterica serotype Typhimurium (S. Typhimurium) is among the Salmonella serotypes most commonly isolated from human and animal salmonellosis cases worldwide [11, 12] and is known to host a range of prophages within its chromosome [10]. Of particular concern is S. Typhimurium phage type DT104 (DT104), a lineage within S. Typhimurium that is known for its typical ampicillin-, chloramphenicol-, streptomycin-, sulfonamide-, and tetracycline-resistant (ACSSuT) phenotype, although its antimicrobial resistance (AMR) profile may vary [13]. Multidrug-resistant (MDR) DT104 is predicted to have emerged circa 1972 [13] and rapidly disseminated around the world in the following decades [13-15], culminating in a global epidemic among animals and humans in the 1990s [13-15].
However, despite its rapid global dissemination, DT104 does not appear to be more virulent than non-DT104 S. Typhimurium in a classical mouse model [16].

In addition to its characteristic MDR phenotype, DT104 is notable for its ability to produce ArtAB, a pertussis-like toxin that catalyzes ADP-ribosylation of host G proteins [17-19]. Treatment of various cell lines with purified ArtAB from DT104 recapitulates some of the phenotypes established for pertussis toxin cytotoxicity [20-22], such as the characteristic “cell clustering” phenotype in CHO-K1 cells [23], increased levels of intracellular cAMP in RAW 264.7 macrophage-like cells [18], and increased serum insulin levels (e.g., insulinemia); further, intraperitoneal injection of purified toxin in neonatal mice was fatal [18]. artAB, which encodes ArtAB, shares a strong association with DT104 relative to other S. Typhimurium lineages, as the overwhelming majority of DT104 possess artAB [18]. However, occasionally, DT104 strains that lack artAB and, thus, the ability to produce ArtAB toxin, have been described [18]; artAB is located on prophages within the DT104 genome [18, 19], indicating that it may be possible for artAB to be lost or gained as a prophage integrates or excises from a genome, or via HGT within an integrated prophage.

In a previous study of S. Typhimurium isolated from dairy cattle and human clinical cases in New York State (United States; U.S.), we identified three bovine- and human-associated DT104 strains, which did not possess artAB (referred to hereafter as “artAB-negative” strains) [24]. Interestingly, these three artAB-negative strains were closely related and formed a clade within the largely artAB-positive New York State DT104 phylogeny [24]. Here, we investigate this lineage further: using (i) 230 human- and bovine-associated DT104 genomes collected across the U.S., plus (ii) 752 DT104 genomes collected from numerous sources worldwide, we identify a major DT104 lineage circulating among cattle and humans across the U.S., which lost
artAB, as well as a co-occurring anti-inflammatory effector encoded by gogB, via a Gifsy-1 prophage loss event that occurred in close temporal proximity to the global MDR DT104 epidemic.

METHODS

Acquisition of U.S. DT104 genomic data and metadata. Genomic data from human- and bovine-associated DT104 isolates from the U.S. were acquired as described previously [24]. Briefly, paired-end Illumina short reads associated with 223 S. Typhimurium genomes meeting the following criteria were downloaded via Enterobase (accessed November 29, 2018) [25, 26] and the Sequence Read Archive (SRA) Toolkit version 2.9.3 [27, 28]: (i) genomes were serotyped as S. Typhimurium in silico using the implementation of SISTR [29] in Enterobase; (ii) the country of isolation was the United States; (iii) the isolation source was reported as either “Human” or “Bovine” in the “Source Niche” and “Source Type” fields in Enterobase, respectively; (iv) genomes had an isolation year reported in Enterobase; (v) genomes were assigned to the same well-supported cluster within the larger bovine- and human-associated U.S. S. Typhimurium phylogeny using RhierBAPS [30] and clustered among known DT104 genomes from other countries (see Supplementary Figures S2 and S5 of Carroll, et al.) [24]. These genomes were supplemented with an additional 14 S. Typhimurium genomes from bovine and human sources in New York State (U.S.) that belonged to the same DT104 cluster (members of the S. Typhimurium Lineage III cluster described in Supplementary Figures S2 and S5 of Carroll, et al.) [24]. Trimmomatic version 0.36 [31] was used to trim low quality bases and Illumina adapters from all read sets using the default settings for paired-end reads, and SPAdes version 3.13.0 [32] was used to assemble all genomes using default settings plus the “careful”
option. FastQC version 0.11.5 [33] and QUAST version 4.0 [34] were used to assess the quality of each read pair set and assembly, respectively, and MultiQC version 1.6 [35] was used to aggregate all FastQC and QUAST results. Trimmed paired-end read sets/assemblies that were flagged by MultiQC as meeting any of the following conditions were excluded: (i) Illumina adapters present after trimming ($n = 2$), (ii) an abnormal per sequence GC content distribution ($n = 3$), (iii) an assembly with over 200 contigs ($n = 11$), and (iv) a sequence quality histogram flagged as poor quality ($n = 2$). After excluding genomes that met these conditions, a set of 219 DT104 genomes was produced for use in subsequent steps (Supplementary Tables S1 and S2).

**Acquisition of global DT104 genomic data and metadata.** To contextualize the 219 U.S. bovine- and human-associated DT104 genomes identified via the initial genome search (see section “Acquisition of U.S. DT104 genomic data and metadata” above) within the larger global DT104 population, genomic data associated with the following studies were downloaded via Enterobase: (i) Illumina reads associated with 243 bovine- and human-associated DT104 isolates from a study of between-host transmission within Scotland [36] (referred to hereafter as the “Scottish DT104” data set); genomes were pre-processed and assembled as described above (see section “Acquisition of U.S. DT104 genomic data and metadata” above); (ii) assembled genomes associated with 290 DT104 isolates from a variety of sources and countries from a study describing the global spread of DT104 [13] (referred to hereafter as the “global DT104” data set; Supplementary Table S1). Overall, these searches resulted in two data sets, which were used in subsequent steps: (i) a 230-genome human- and bovine-associated U.S. DT104 data set (i.e., 219 genomes identified in this study, plus 11 additional U.S. bovine- and human-associated DT104 strains from the 290-genome “global DT104” data set, which did not have metadata available in Enterobase at the time and were thus not included in the initial set of bovine- and human-
associated U.S. DT104 genomes; see section “Acquisition of U.S. DT104 genomic data and metadata” above); (ii) a 752-genome data set, composed of genomes from all three data sets (i.e., 219 genomes identified in this study, 243 Scottish DT104 genomes, and 290 global DT104 genomes, referred to hereafter as the “combined DT104” data set; Supplementary Tables S1 and S2). QUAST version 4.5 was used to assess the quality of all 752 genomes (Supplementary Tables S1 and S2).

**In silico detection of antimicrobial resistance genes, plasmid replicons, virulence factors, and prophage.** To identify putative prophage regions in all 752 genomes, each assembly was submitted to the PHASTER web server via the URL API [37, 38] with the “contigs” option set to “1”. ABRicate version 0.8 [39] was used to detect antimicrobial resistance (AMR) genes, plasmid replicons, and virulence factors in each assembled DT104 genome using NCBI’s National Database of Antibiotic Resistant Organisms (NDARO) [40], the PlasmidFinder database [41], and the Virulence Factor Database (VFDB) [42], respectively, using minimum nucleotide identity and coverage thresholds of 75 and 50%, respectively (all databases accessed December 10, 2020; Supplementary Table S3). The aforementioned ABRicate analyses were repeated, using a minimum coverage threshold of 0% (e.g., to confirm that virulence factors discussed in the manuscript were absent from genomes in which they were not initially detected).

Each assembled genome was additionally queried for the presence of selected virulence factors, which have previously been associated with prophage in *Salmonella* [43]: (i) *artAB* (NCBI Nucleotide Accession AB104436.1), (ii) *gogA* (European Nucleotide Archive [ENA] Accession EAA785092.1), (iii) *gtgA* (ENA Accession PVI70081.1), and (iv) *gipA* (ENA Accession CAI93790.1). Assembled genomes were queried for selected virulence factors using the command-line implementation of nucleotide BLAST (blastn) version 2.11.0 [44], using
default settings plus a minimum coverage threshold of 40% (Supplementary Table S3). To confirm that the aforementioned genes were absent from genomes in which they were not initially detected, all genomes were queried again (i) as described above, with the coverage threshold lowered to 0%; (ii) using translated nucleotide BLAST (tblastx; e.g., to confirm that all genomes in the U.S. artAB-negative major clade did not possess remote artAB and gogB homologs; Supplementary Tables S4 and S5).

Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set. Core SNPs were identified among genomes within the 230-genome human- and bovine-associated U.S. DT104 data set using the default pipeline implemented in Snippy version 4.6.0 [45] and the following dependencies: BWA version 0.7.17-r1188 [46, 47], Minimap2 version 2.23-r1111 [48], SAMtools version 1.14 [49], BEDtools version 2.30.0 [50, 51], BCFtools version 1.14 [52], FreeBayes version 1.3.2-dirty [53], vcflib version 1.0.0-rc0-349-g45c6-dirty [54], vt version 0.5 [55], SnpEff version 5.0e [56], samclip version 0.4.0 [57], seqtk version 1.3-r106 [58], and snp-sites version 2.5.1 [59]. For the 219 U.S. genomes initially identified in this study, the trimmed Illumina paired-end reads associated with each genome were treated as input; for the remaining genomes, the assembled contigs were used as input (see sections “Acquisition of U.S. DT104 genomic data and metadata” and “Acquisition of global DT104 genomic data and metadata” above; Supplementary Tables S1 and S2). The closed DT104 chromosome (NCBI Nucleotide Accession NC_022569.1) was treated as a reference. Core SNPs identified in regions of the DT104 chromosome predicted to belong to phage were masked (see section “In silico detection of antimicrobial resistance genes, plasmid replicons, virulence factors, and prophage” above). Gubbins version 2.4.1 [60] was used to identify and
remove recombination events among all genomes using default settings, and snp-sites was used to query the resulting recombination-free alignment for core SNPs (i.e., using the “-c” option).

A maximum likelihood (ML) phylogeny was constructed with IQ-TREE version 1.5.4 [61], using (i) the resulting core SNPs as input, (ii) the optimal nucleotide substitution model determined using Bayesian information criteria (BIC) values produced with ModelFinder [62] (i.e., the K3Pu+I model) [63], (iii) an ascertainment bias correction to account for the use of solely variant sites (corresponding to constant sites identified relative to the DT104 reference chromosome; -fconst 1092869,1195194,1193287,1094079), and (iv) 1,000 replicates of the ultrafast bootstrap approximation [64, 65].

TempEst version 1.5.3 [66] was used to assess the temporal structure of the resulting unrooted ML phylogeny, using the best-fitting root and the $R^2$ function ($R^2 = 0.33$, slope = $3.05 \times 10^{-7}$ substitutions/site/year, X-intercept = 1988.1). The unrooted ML phylogeny was additionally rooted and time scaled using LSD2 version 1.4.2.2 [67] and the following parameters: (i) tip dates corresponding to the year of isolation associated with each genome; (ii) an estimated substitution rate; (iii) constrained mode (-c), with the root estimated using constraints on all branches (-r as); (iv) variances calculated using input branch lengths (-v 1); (v) 1,000 samples for calculating confidence intervals for estimated dates (-f 1000); (vi) a sequence length of 4,500,000. The resulting rooted, time-scaled ML phylogeny was viewed using FigTree version 1.4.4 [68] (Supplementary Data).

**Variant calling and maximum likelihood phylogeny construction within the combined DT104 data set.** Parsnp and HarvestTools version 1.2 [69] were used to detect core SNPs among all 752 assembled DT104 genomes within the combined DT104 data set (see section “Acquisition of global DT104 genomic data and metadata” above; Supplementary Tables S1 and
S2), using the closed DT104 chromosome as a reference (NCBI Nucleotide Accession NC_022569.1) and Parsnp’s implementation of PhiPack [70] to filter recombination. Core SNPs detected among all 752 assembled genomes were supplied as input to IQ-TREE version 1.5.4, which was used to construct a ML phylogeny as described above (the corresponding ascertainment bias correction here was “-fconst 1181208,1285673,1280769,1179580”; see section “Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set” above). The resulting ML phylogeny was rooted and time-scaled using LSD2 as described above (see section “Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set” above). A range of 1900-2017 was supplied for four genomes, which were part of the global DT104 data set, but did not have a reported year of isolation. The resulting time-scaled ML phylogeny was annotated using the Interactive Tree of Life (iTOL) version 6 webserver (https://itol.embl.de/; accessed March 7, 2022) [71].

U.S. DT104 Bayesian time-scaled phylogeny construction. Due to the overrepresentation of genomes of DT104 strains reportedly isolated in 2007 from bovine sources in Washington state within the 230-genome human- and bovine-associated U.S. DT104 data set (Figure 1 and Supplementary Table S1), all aforementioned SNP calling and phylogeny construction steps were repeated among genome sets downsampled to (i) 25, (ii) 10, and (iii) 5 randomly selected bovine DT104 genomes collected in Washington state in 2007 (n = 161, 146, and 141 total genomes in each downsampled genome set, respectively; see section “Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set” above, Supplementary Data). For each of the three downsampled U.S. DT104 data sets, BEAST2 version 2.5.1 [72, 73] was used to construct a tip-dated phylogeny using core SNPs detected among the genomes within the respective data set as input (see section “Variant calling and
maximum likelihood phylogeny construction within the U.S. DT104 data set” above), an initial
clock rate of $2.79 \times 10^{-7}$ substitutions/site/year [13], and an ascertainment bias correction to
account for the use of solely variant sites [74]. bmodeltest [75] was used to infer a substitution
model using Bayesian model averaging, with transitions and transversions split. A relaxed
lognormal molecular clock [76] and a coalescent Bayesian skyline population model [77] were
used, as these models have been selected as the optimal clock/population model combination for
DT104 previously [13]. A log-normal distribution with a mean of $4.6 \times 10^{-7}$ and standard
deviation of 1 (median of $2.79 \times 10^{-7}$) was used as the prior on the uncorrelated log-normal
relaxed molecular clock mean rate parameter (ucld.mean; Supplementary Data).

For each of the three downsampled U.S. DT104 data sets, five independent BEAST2 runs
were performed, using chain lengths of at least 100 million generations, sampling every 10
thousand generations. For each downsampled data set, LogCombiner-2 was used to aggregate the
resulting log and tree files with 10% of the states treated as burn-in, and TreeAnnotator-2 was
used to produce a maximum clade credibility (MCC) tree using Common Ancestor node heights
(Supplementary Data). The resulting phylogenies was displayed and annotated using R version
4.1.2 [78] and the following packages: ggplot2 version 3.3.5 [79], ggtree version 3.2.1 [80, 81],
phylobase version 0.8.10 [82], and treeio version 1.18.1 [83].

All three downsampled U.S. DT104 data sets resulted in similar BEAST2 parameter
estimates (Supplementary Figure S1, Supplementary Table S6, and Supplementary Data). Thus,
the final Bayesian time-scaled phylogeny and associated parameter estimates reported in the
main manuscript correspond to those obtained using the U.S. DT104 data set, which was
downscaled to 10 randomly selected bovine DT104 genomes collected in Washington state in
2007 ($n = 146$ genomes, Figures 2 and 3). Results are available for the U.S. DT104 data sets
downsampled to 25 and 5 bovine DT104 genomes collected in Washington state in 2007 (Supplementary Figures S2-S5, Supplementary Table S6, and Supplementary Data).

**artAB ancestral state reconstruction.** To estimate ancestral character states of internal nodes in the (i) U.S. DT104 and (ii) combined DT104 data set phylogenies as they related to artAB presence/absence (i.e., whether a node in the tree represented an ancestor that was more likely to be artAB-positive or artAB-negative), the presence or absence of artAB within each genome was treated as a binary state. The following phylogenies were each used as input: (i) the BEAST2 time-scaled Bayesian U.S. DT104 phylogenies ($n = 161, 146, \text{ and } 141$ total genomes in each downsampled data set; see section “U.S. DT104 Bayesian time-scaled phylogeny construction” above); (ii) the LSD2 time-scaled ML combined DT104 data set phylogeny ($n = 752$; see section “Variant calling and maximum likelihood phylogeny construction within the combined DT104 data set” above). Stochastic character maps were simulated on each phylogeny using the make.simmap function in the phytools version 1.0-1 R package [84] and the all-rates-different (ARD) model in the ape version 5.6-1 package. For each phylogeny, either (i) equal root node prior probabilities for artAB-positive and artAB-negative states (i.e., $P(\text{artAB present}) = P(\text{artAB-absent}) = 0.5$), or (ii) estimated root node prior probabilities for artAB-positive and artAB-negative states obtained using the make.simmap function were used. For each root node prior/phylogeny combination (eight total combinations of two root node priors and four phylogenies), an empirical Bayes approach was used, in which a continuous-time reversible Markov model was fitted, followed by 10,000 simulations of stochastic character histories using the fitted model and tree tip states. The resulting phylogenies were plotted using the densityMap function in the phytools R package. For the U.S. DT104 data set, the final ancestral state results reported in the main manuscript correspond to those obtained using the U.S. DT104 data set,
which was downsampled to 10 randomly selected bovine DT104 genomes collected in Washington state in 2007 \( (n = 146 \text{ genomes, Figure 2}) \). Results are available for the U.S. DT104 data sets downsampled to 25 and 5 bovine DT104 genomes collected in Washington state in 2007 (Supplementary Figures S6-S10 and Supplementary Data).

**Pan-genome characterization.** Prokka version 1.13.3 [85] was used to annotate all 752 DT104 genomes, using the “Bacteria” database (see section “Genomic comparison of U.S. DT104 to the global DT104 population” above; Supplementary Tables S1 and S2). GFF files produced by Prokka were supplied as input to Panaroo version 1.2.7 [86], which was used to identify core- and pan-genome orthologous gene clusters among (i) the 230 U.S. DT104 genomes and (ii) all 752 DT104 genomes in the combined data set, using the following parameters: (i) “strict” mode (--clean-mode strict); (ii) MAFFT as the sequence aligner (--aligner mafft) [87, 88]; (iii) a core genome threshold of 98% (i.e., genes present in at least 98% of genomes were considered to be core genes; --core_threshold 0.98); (iv) a protein family sequence identity threshold of 70% (-f 0.7, the default). The LSD2 time-scaled ML phylogenies for the (i) 230-genome U.S. DT104 and (ii) combined DT104 data sets (see sections “Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set” and “Variant calling and maximum likelihood phylogeny construction within the combined DT104 data set” above) were supplied as input to Panaroo’s “panaroo-img” and “panaroo-fmg” commands, which were used to estimate the pan-genome size under the Infinitely Many Genes (IMG) [89, 90] and Finite Many Genes (FMG) models (with 100 bootstrap replicates) [91], respectively (Supplementary Figure S11). Reference pan-genome coding sequences (CDS) identified by Panaroo for both the (i) U.S. and (ii) combined DT104 data sets underwent functional annotation using the eggNOG-mapper version 2 webserver (http://eggnog-mapper.embl.de/; accessed July 24, 2022) using default settings [92,
Among genomes within the U.S. DT104 data set ($n = 230$), the “table” function in R was used to identify genes associated with (i) Gifsy-1 presence/absence (Supplementary Table S7) and (ii) major clade membership (Supplementary Table S8); the “fisher.test” function in R’s stats package was used to conduct two-sided Fisher’s exact tests, and the “p.adjust” function was used to control the false discovery rate (i.e., $p$-adjust method = “fdr”) [94].

The treewas version 1.0 R package [95] was additionally used to identify potential gene-host associations among the 230-genome U.S. DT104 data set (i.e., whether a gene identified with Panaroo was human- or bovine-associated while accounting for population structure), using the following: (i) the isolation source treated as a discrete phenotype (i.e., a vector of “human” or “bovine”, supplied to the treeWAS function’s “phen” argument; phen.type = “discrete”); (ii) unique gene presence/absence profiles of genes detected in $\geq 10$ and $\leq 220$ of 230 total U.S. DT104 genomes, treated as the genotypes to test (supplied to the treeWAS function’s “snps” argument); (iii) the time-scaled ML phylogeny constructed using LSD2 for the treeWAS function’s “tree” argument (see section “Variant calling and maximum likelihood phylogeny construction within the U.S. DT104 data set” above); (iv) the number of simulated loci for estimating the null distribution set to five million (i.e., $n$.snps.sim = $5000000$); (v) ancestral state reconstruction performed using ML methods (i.e., snps.reconstruction = “ML”, snps.sim.reconstruction = “ML”, and phen.reconstruction = “ML”); (vi) a $P$-value significance threshold of 0.1, after controlling the FDR ($p$.value.correct = ”fdr”). The analysis was re-run, using parsimony approaches in place of ML approaches for ancestral state reconstruction. Regardless of approach, no genes were found to be significantly associated with isolation source via any of the treeWAS association tests (FDR-corrected $P > 0.1$).
Strain selection for phenotypic stress assays. Thirteen DT104 strains isolated from a previous study of S. Typhimurium in New York State [24], which were each available in the Cornell University Food Safety Laboratory (CUFSL) culture collection [96], were additionally characterized separately so that Gifsy-1/artAB/gogB-positive and -negative DT104 strains from bovine and human sources in the U.S. could be selected to undergo phenotypic characterization (Supplementary Table S9). Parsnp and HarvestTools version 1.2 [69] were used to identify core SNPs among all 13 assembled genomes, using the closed DT104 chromosome as a reference (NCBI Nucleotide Accession NC_022569.1) and Parsnp’s implementation of PhiPack [70] to remove recombination. IQ-TREE version 1.5.4 was used to construct a ML phylogeny, using (i) the resulting core SNPs as input, (ii) an ascertainment bias correction, based on the GC content of the DT104 reference chromosome (-fconst 1182070,1287912,1283169,1180480), (iii) the optimal nucleotide substitution model (-m MFP), selected using ModelFinder (i.e., the TIM+I model), and (iv) 1,000 replicates of the ultrafast bootstrap approximation (-bb 1000). Prokka version 1.13 was used to annotate each genome (using the “Bacteria” database), and the resulting GFF files were supplied to Roary version 3.13.0 [97], which was used to identify orthologous gene clusters among the 13 DT104 genomes (using default thresholds, e.g., 95% BLASTP identity).

The New York State DT104 isolates differed little in terms of their core and pan-genome compositions (Supplementary Figure S12 and Supplementary Table S9). A total of 336 core SNPs were identified among the 13 DT104 genomes; pairwise core SNP distances between all 13 genomes ranged from 12-113 core SNPs (median and mean of 85 and 80.8 core SNPs, respectively, calculated using the “dist.gene” function in the ape R package). Based on gene presence/absence of pan-genome elements, the Jaccard distance between all 13 genomes ranged

...
from 0.0036-0.0820 (median and mean of 0.0359 and 0.0380, respectively; calculated in R using the “vegdist” function in vegan version 2.5-7) [98].

All available Gifsy-1/artAB/gogB-negative strains in the CUFSL culture collection were selected to undergo phenotypic testing ($n = 3$, two human isolates and one bovine isolate; Supplementary Table S9); all three strains were members of the U.S. artAB-negative major clade (discussed in detail below). Considering both core and pan-genome distances relative to all three available Gifsy-1/artAB/gogB-negative strains, three Gifsy-1/artAB/gogB-positive DT104 strains were additionally selected to undergo phenotypic testing (one from human and two from bovine sources; Supplementary Figure S12 and Supplementary Table S9). The three selected Gifsy-1/artAB/gogB-positive DT104 strains differed from the three available Gifsy-1/artAB/gogB-negative strains by (i) 64-83 (HUM_TYPH NY_04_S5_0370), 74-93 (BOV_TYPH NY_99_A4_0023), and 65-84 (BOV_TYPH NY_99_S3_0910) core SNPs and (ii) Jaccard distances (based on pan-genome element presence/absence) of 0.0148-0.0610 (HUM_TYPH NY_04_S5_0370), 0.0174-0.0622 (BOV_TYPH NY_99_A4_0023) and 0.0163-0.0620 (BOV_TYPH NY_99_S3_0910; Supplementary Figure S12).

Phenotypic assays. All strain stocks (Supplementary Table S9) were maintained in CRYOBANK® tubes (Mast Ltd., Reinfeld, Germany) at -80°C. Strains were streaked out from stocks on tryptic soy agar (TSA; Merck KGaA, Darmstadt, Germany) and incubated overnight at 37°C. Single colonies from those plates were inoculated in 5 mL of tryptic soy broth (TSB; Merck KGaA, Darmstadt, Germany) and incubated for 16 - 18 h at 37°C with shaking at 200 rpm. The resulting overnight cultures were diluted 1/100 into 5 mL of fresh, pre-warmed TSB, followed by incubation at 37°C with shaking at 200 rpm to allow cultures to reach mid log phase (defined as OD$_{600}$ of 0.4; 1-2 x10$^8$ CFU/mL). These cultures were used as input into the three
different phenotypic assays (exposure to ruminal fluid, acid stress, and bile stress; discussed in detail below). Bacterial enumeration before and after stress exposure was performed by direct colony counts of tilt plates according to Kühbacher et al. [99].

To evaluate exposure to ruminal fluid (RF), approximately 2 L of RF was acquired from a Jersey cow with a ruminal fistula on each experimental day prior to the experiments (same collection time was used for each experiment). The RF was immediately filtered through a cellulose filter (Labsolute® Type 80, Th. Geyer GmbH& Co. KG., Renningen, Germany) to remove any large debris, and the pH was measured, ranging from 7.20 to 7.62. Mid-log phase cultures were prepared and inoculated into the RF at two different concentrations. One hundred µl of culture suspensions were inoculated into 5mL of the RF at final concentrations of $10^8$ (high) and $10^5$ (low) CFU/mL and incubated for 1 h at 37°C without shaking with enumeration by direct colony counting on XLT-4 agar (Oxoid Ltd., Basingstoke, UK) prior and after RF exposure (Supplementary Table S10). The absence of *Salmonella* in the RF at the start of the experiments was confirmed by plating on XLT-4 agar.

Acid stress resistance of the different strains at pH 3.5 with and without prior adaption was tested using an adopted protocol from Horlbog et al. [100]. The pH of the TSB was adjusted with hydrochloric acid solution (1M and 6 M HCL; Merck KGaA, Darmstadt, Germany) immediately prior to the experiment. 1 mL aliquots of mid log phase cultures were transferred to reaction tubes and centrifuged at 14,000 x g for 10 min. For the non-adapted acid stress experiments, the pellets were resuspended in 1mL TSB pH 3.5 and incubated for 1 h at 37°C without shaking. For acid adaption, 1 mL of the same cultures were pelleted, resuspended in 1 mL TSB adjusted to pH 5.5 and incubated for 1h at 37°C (without shaking). Afterwards, the cultures were centrifuged again, resuspended in 1mL TSB pH 3.5, and incubated for 1 h at 37°C.
without shaking. Bacteria enumeration was performed before and after the one-hour incubation
at pH 3.5 (Supplementary Table S11).

Susceptibility to bile salts (cholic acid and deoxycholic acid in a mixture of 1:1, Bile
Salts No.3, Thermo Fisher Scientific Inc., Waltham, USA) was tested in two different
concentrations: 14.5 mmol/L corresponding to 0.6% [101] and 26.0 mmol/L corresponding to
1.1% [102] were chosen to represent reasonable physiological states in the duodenum. Bile salts
were added, and the pH of the TSB was adjusted to 5.5 (TSB-bile) immediately prior to the
experiment. Mid log phase cultures were centrifuged, resuspended in TSB-bile, incubated for 1h
37°C without shaking, and enumerated by direct colony counting prior and after bile exposure
(Supplementary Table S12).

For each stress assay, base-ten logarithmic fold change (FC) values were calculated as
follows: $FC = \log \text{CFU/g at the start of the experiments} - \log \text{CFU/g after the stress assay}$.
Analysis of Variance (ANOVA) for the interpretation of the phenotypic assays were conducted
using the “aov” function in R’s “stats” package, with the FC values for the respective assay
treated as a response. Figures were designed using the ggplot2 package.

**Data availability.** Strain metadata, genome quality metrics, and Enterobase accession numbers
for all publicly available genomes queried in this study are available in Supplementary Table S1.
Strain metadata, genome quality metrics, Food Microbe Tracker IDs, and NCBI BioSample
accession numbers for the 13 NYS DT104 strains queried in this study (including those queried
via phenotypic assays) are available in Supplementary Table S2. LSD2 results (for the U.S. and
combined DT104 data sets) and BEAST2 results (for the U.S. DT104 data set) are available as
Supplementary Data.
RESULTS

Human- and bovine-associated DT104 from the U.S. harbor artAB on prophage Gifsy-1.

Within the set of 230 human- and bovine-associated DT104 genomes derived from strains isolated in the U.S. (62 and 168 genomes from human and bovine sources, respectively; Figure 1A) [24], artAB was present in over 75% of genomes (177 of 230, 77.0%; Figure 2, Table 1, and Supplementary Figures S2-S4). artAB presence and absence was strongly associated with the presence and absence of anti-inflammatory effector gogB (two-sided Fisher’s Exact Test raw $P < 2.2 \times 10^{-16}$, infinite odds ratio [OR]), as co-occurrence was observed in all 177 artAB-harboring genomes (100.0%; Figure 2, Table 1, and Supplementary Figures S2-S4). Additionally, artAB and gogB presence was strongly associated with the presence of prophage Gifsy-1 (NCBI Nucleotide Accession NC_010392.1; two-sided Fisher’s Exact Test raw $P < 2.2 \times 10^{-16}$, infinite OR; Figure 2, Table 1, and Supplementary Figures S2-S4). Subsequent investigation confirmed that, for all 177 artAB-harboring U.S. DT104 genomes, artAB was located within the Gifsy-1 prophage region (classified as “intact” via PHASTER; Table 2 and Supplementary Table S5). gogB was largely harbored within regions annotated as Gifsy-1 (126 of 180 gogB-harboring genomes; 70.0%), although only 51 of these Gifsy-1 regions were annotated as intact prophage (via PHASTER, 28.3% of gogB-harboring genomes; Table 2 and Supplementary Table S5). Occasionally, gogB was detected elsewhere in the genome: three genomes harbored gogB within regions annotated as prophage Gifsy-2 (3 of 180 gogB-harboring genomes, 1.7%; Table 2 and Supplementary Table S5), while gogB was detected outside of annotated prophage regions within the remaining 51 gogB-harboring genomes (28.3% of gogB-harboring genomes; Table 2 and Supplementary Table S5).
Only three genomes (bovine-associated BOV_TYPH_Washington_2007_SRR1519881, BOV_TYPH_Minnesota_2010_SRR1089590, and BOV_TYPH_Minnesota_2008_SRR1177378) possessed an intact Gifsy-1 prophage but did not possess artAB (1.7% of genomes in which an intact Gifsy-1 was detected), although all three genomes possessed gogB (gogB was detected within an incomplete Gifsy-1 prophage region in the two genomes from Minnesota, while the genome from Washington did not harbor gogB within an annotated prophage region; Figure 2, Tables 1 and 2, Supplementary Figures S2-S4, and Supplementary Table S5). Of the 168 bovine-associated DT104 genomes from the U.S., 150 (89.3%) possessed artAB, gogB, and Gifsy-1, while 153 (91.1%) possessed gogB and Gifsy-1 (Figure 2, Table 1, and Supplementary Figures S2-S4). Interestingly, of 62 human-associated genomes, only 27 (43.5%) possessed artAB, gogB, and Gifsy-1 (Figure 2, Table 1, and Supplementary Figures S2-S4), indicating that Gifsy-1/artAB/gogB may share a negative association with human-associated DT104 from the U.S. (two-sided Fisher’s Exact Test raw P < 4.1×10^{-12}, OR = 10.6; Table 1); however, no genes within the U.S. DT104 pan-genome shared a significant association with bovine or human host when accounting for population structure (treeWAS FDR-corrected P > 0.10).

Overall, 90 genes within the U.S. DT104 pan-genome were associated with Gifsy-1 presence or absence (two-sided Fisher’s exact test FDR-corrected P-value < 0.05; Supplementary Figure S11 and Supplementary Table S7). The presence and absence of 30 genes shared a perfect association with Gifsy-1 presence and absence (i.e., these genes were absent from all U.S. DT104 genomes that did not possess Gifsy-1 and were present in all U.S. DT104 genomes that did possess Gifsy-1; FDR-corrected P < 0.05 and OR of infinity); in addition to gogB, these genes included numerous phage-associated proteins (Supplementary Table S7).
A MDR DT104 lineage circulating among cattle and humans across the U.S. lost prophage Gifsy-1 in close temporal proximity to a period of rapid DT104 population growth in the 1980s. To gain insight into the evolutionary relationships of artAB-negative U.S. DT104 strains, a time-scaled phylogeny was constructed using human- and bovine-associated U.S. DT104 genomes (Figure 2 and Supplementary Figures S2-S4). The common ancestor shared by all MDR U.S. bovine- and human-associated DT104 isolates included in this study was predicted to have existed circa 1975 (estimated node age 1974.9, node height 95% highest posterior density [HPD] interval [1958.1, 1986.4]; Figure 2 and Supplementary Figures S2-S4), which is consistent with observations in previous studies [13, 103], in which DT104 was predicted to have acquired its MDR phenotype in the 1970s. The mean evolutionary rate estimated for the U.S. DT104 queried here was $1.75 \times 10^{-7}$ substitutions/site/year (95% HPD interval [$1.38 \times 10^{-7}$, $2.11 \times 10^{-7}$]), which is similar to evolutionary rates estimated in previous studies of DT104 isolates from other world regions [13, 36] (Supplementary Figure S1, Supplementary Table S6, and Supplementary Data).

Notably, over 75% of all U.S. DT104 artAB-negative genomes (42 of 53 artAB-negative genomes, 79.2%) were members of a single, well-supported clade (posterior probability = 1.0, referred to hereafter as the “U.S. artAB-negative major clade”; Figure 2 and Supplementary Figures S2-S4). In addition to lacking artAB, all members of the U.S. artAB-negative major clade lacked Gifsy-1 and 50 additional genes, which were present in over half of U.S. DT104 genomes not included in the U.S. artAB-negative major clade, including gogB, a chitinase, and many phage-associated proteins (Figure 2, Supplementary Figures S2-S4, and Supplementary Table S8). Strains within the U.S. artAB-negative major clade were reported to have been isolated between 1997 and 2018 (the most recent year included in this study) from at least 11
different states across the U.S. (for two isolates, the U.S. state in which the strain was isolated was unknown; Figures 1B and 2 and Supplementary Figures S2-S4). Most strains within the U.S. artAB-negative major clade were isolated from human clinical cases ($n = 30$ of 42 U.S. artAB-negative major clade strains, 71.4%), and nearly half of all U.S. DT104 strains isolated from human sources were members of this clade ($n = 30$ of 62 U.S. DT104 strains from human sources, 48.4%); bovine strains within the U.S. artAB-negative major clade were isolated from bovine clinical cases or beef products ($n = 12$ of 42 strains, 28.6%; Figure 2, Supplementary Figures S2-S4, and Supplementary Table S1).

Based on results of ancestral state reconstruction using artAB presence/absence, the loss of Gifsy-1, artAB, gogB, and other Gifsy-1-associated genes among members of the U.S. artAB-negative major clade was estimated to have occurred between 1985 and 1987 (estimated node ages 1985.0 and 1987.2, node height 95% HPD intervals [1979.0, 1990.2] and [1981.7, 1992.1], respectively; Figure 2 and Supplementary Figures S6-S8). Interestingly, this predicted loss event occurred in close temporal proximity to a rapid increase in the effective population size of U.S. DT104, which occurred in the mid-to-late 1980s (Figure 3 and Supplementary Figure S5).

Following this predicted rapid increase in the 1980s, the U.S. DT104 effective population size was predicted to have increased again in the mid-to-late 1990s, peaking circa 2000 (Figure 3 and Supplementary Figure S5).

**Loss of artAB and gogB within the global DT104 population occurs sporadically.** The absence of Gifsy-1, artAB, and/or gogB among DT104 strains was not strictly a U.S. phenomenon: Gifsy-1, artAB, and gogB were not detected in 19 and three genomes out of (i) 290 DT104 strains collected from numerous sources around the world [13] and (ii) 243 DT104 strains isolated from cattle and humans in Scotland [36], respectively (representing 6.6% and
1.2% of strains in their respective study that were included in our analysis here; Figure 4 and Supplementary Figures S9 and S10). However, the Gifsy-1/artAB/gogB loss event associated with the U.S. artAB-negative major clade represented the single largest Gifsy-1/artAB/gogB loss event (n = 42; Figure 4 and Supplementary Figures S9 and S10).

Among all 752 DT104 genomes queried here, the presence and absence of artAB and gogB was correlated with that of Gifsy-1 (two-sided Fisher’s Exact Test raw P < 2.2 × 10^{-16} for each, ORs of 2069.8 and infinity, respectively), as well as each other (two-sided Fisher’s Exact Test raw P < 2.2 × 10^{-16}, infinite OR; Figure 4, Table 1, and Supplementary Figure S9). However, unlike the 177 artAB-harboring U.S. genomes queried here, artAB were not always detected within prophage regions annotated as Gifsy-1 in the other genomes (Table 2 and Supplementary Table S5).

In vitro response to human- and bovine-associated gastrointestinal stress factors is not correlated with the presence of artAB, gogB, and Gifsy-1 in U.S. DT104. The (i) loss of Gifsy-1/artAB/gogB associated with the U.S. artAB-negative major clade in close temporal proximity to a predicted rapid increase in the DT104 effective population size, plus (ii) the over-representation of human strains in this clade led us to hypothesize that ArtAB and/or GogB production (or some other genomic element harbored on Gifsy-1) may influence the dynamics of DT104 in the digestive tracks of human and animal hosts. Thus, we used phenotypic assays that simulate human and/or bovine digestion-associated stress conditions to compare the phenotypes of Gifsy-1/artAB/gogB-negative members of the U.S. artAB-negative major clade to those of the most closely related Gifsy-1/artAB/gogB-positive U.S. DT104 strains available (Supplementary Table S9).
As the first three compartments of the bovine digestive tract differ massively from that in the human gut, the phenotype of Gifsy-1/artAB/gogB-positive and -negative strains was investigated in fresh bovine ruminal fluid (RF) obtained from a donor cow (Supplementary Table S10). DT104 concentrations were reduced by 3.4 log CFU (SD=0.2) when inoculated into RF at a final concentration of $10^5$ CFU/mL, whereas DT104 numbers were reduced by 1.3 log CFU (SD = 0.2) when inoculated at a final concentration of $10^8$ CFU/mL. While the inoculation density did significantly affect survival (ANOVA raw $P < 0.001$), the phenotype in RF was not associated with the presence or absence of Gifsy-1/artAB/gogB (ANOVA raw $P > 0.05$; Figure 5).

The presence of Gifsy-1/artAB/gogB also did not significantly influence acid stress survival at pH 3.5 (ANOVA raw $P > 0.05$; Figure 5 and Supplementary Table S11). While prior adaptation at an intermediate pH 5.5 significantly increased survival at pH 3.5 as expected (ANOVA raw $P < 0.01$), there was no significant difference in acid adaptation between Gifsy-1/artAB/gogB-positive and -negative strains (ANOVA raw $P > 0.05$; Figure 5). Both groups showed a concentration-dependent reduction in growth/survival at the two tested bile concentrations of 0.6% and 1.1% (ANOVA raw $P = 0.01$ for the difference in fold change at the two concentrations), but there was no Gifsy-1/artAB/gogB-dependent phenotype in the response of DT104 strains to bile stress (ANOVA raw $P > 0.05$; Figure 5 and Supplementary Table S12).

**DISCUSSION**

A DT104 lineage distributed across multiple U.S. states lost its ability to produce toxin ArtAB in close temporal proximity to the global DT104 epidemic. Bacterial ADP-ribosylating toxins play important roles in the virulence of numerous pathogens [19, 104]. While
the illness caused by *Salmonella enterica* is not considered to be a toxin-mediated disease in the
classical sense (e.g., as is the case for *Clostridium botulinum* or *Vibrio cholerae*) [19], some
*Salmonella* lineages are capable of producing ADP-ribosylating toxins, allowing them to alter
host immune responses and promote pathogenesis [17, 19, 105-107]. ArtAB is one such toxin
with a variable presence among *Salmonella* lineages; genes encoding ArtAB have been detected
in at least 45 different serotypes and are correlated with the presence of typhoid toxin genes,
although in DT104 this is not the case [108]. Additionally, in the majority of these serotypes,
*artA* is predicted to be a pseudogene and the selective advantage of maintaining *artB* appears to
be related to its use as an alternative binding subunit for the typhoid toxin [19, 109].

A previous study of ArtAB-producing DT104 strains [18] found that ArtAB production
among DT104 appears to be the norm rather than the exception, as 237 of 243 strains (97.5%) in
the study were *artAB*-positive [18]. We observed similar findings here, as *artAB* was detected in
678 of 752 DT104 genomes (90.2%). However, we additionally showed that *artAB* loss events
appear sporadically throughout the DT104 phylogeny (Figures 2 and 4 and Supplementary
Figures S9 and S10). Among U.S. DT104, these loss events usually coincided with Gifsy-1
excision, although not exclusively (i.e., three strains did not possess *artAB*, but possessed Gifsy-1;
*artAB* loss events appear sporadically throughout the DT104 phylogeny (Figures 2 and 4 and Supplementary
Figures S9 and S10). Among U.S. DT104, these loss events usually coincided with Gifsy-1
excision, although not exclusively (i.e., three strains did not possess *artAB*, but possessed Gifsy-1;
Figure 2 and Supplementary Figures S2-S4).

Most notably, we observed a MDR DT104 clade circulating among cattle and humans
across 11 U.S. states, which lost Gifsy-1, along with the ability to produce ArtAB and GogB,
(i.e., the U.S. *artAB*-negative major clade; Figure 2). The U.S. *artAB*-negative major clade was
predicted to have lost Gifsy-1/*artAB*/gogB circa 1985-1987, which is in close temporal proximity
to the predicted rapid increase in the U.S. DT104 effective population size, which occurred in the
mid-to-late 1980s (Figure 3). Our results are consistent with a previous study of DT104 from
multiple world regions, which also identified periods of dramatic population growth in the 1980s and 1990s [13]. This rapid increase in population size is notable, as it coincides with the global MDR DT104 epidemic, which occurred among humans and animals throughout the 1990s [13, 14, 36]. However, it is essential to note that any potential association between the virulence and/or fitness of MDR DT104 and Gifsy-1/artAB/gogB loss among DT104 is merely speculative at this point (discussed in detail below); while previous studies of DT104 have shown that prophage excision and artAB loss occur in response to DNA damage and other stressors [17, 19], future studies are needed to better understand the roles that Gifsy-1, artAB, and gogB play in DT104 evolution.

Members of the U.S. artAB-negative major clade do not have a phenotypic advantage relative to other U.S. DT104 when exposed to ruminal fluid-, acid-, and bile-associated stressors in vitro. *Salmonella enterica* encounters numerous stressors within the gastrointestinal tracts of humans and animals, including (but not limited to) low pH, low oxygen, exposure to bile, and the host immune system [110-112]. Furthermore, the gastrointestinal environment that *Salmonella enterica* encounters can differ between hosts; for example, the first three compartments of the bovine digestive tract differ massively from those of the human gut, as they essentially serve as massive microbial fermentation chambers [113]. Here, we evaluated DT104 survival when exposed to three stressors encountered in the human and/or bovine gastrointestinal tracts: (i) ruminal fluid (RF; bovine rumen), (ii) low pH (bovine abomasum and human stomach), and (iii) exposure to bile (bovine and human duodenum); we discuss each step in detail below.

In the bovine digestion process, the RF, including the complex community of ruminal microbiota [114], presents an early line of defense against potential pathogens, like *Salmonella* spp. In RF, the kill rate of DT104 strains was dependent on the inoculation density. The high
inoculation rate ($10^8$ CFU/mL) was chosen to test the ability of the ruminal microbiota to efficiently kill or impede *Salmonella*. The lower inoculation rate of $10^5$ CFU/mL was chosen for its dynamic range to measure either growth or decrease of *Salmonella* concentration. An interaction of the complex ruminal microbiota with the inoculated *Salmonella* is conceivable in two ways: either the microbiota exhibit strategies to produce antimicrobial compounds against *Salmonella* species [115, 116], or through competition for nutrients, e.g., iron [117]. The fact that the ruminal microbiota was less effective at killing DT104 at the high inoculation rate suggests that their defense mechanisms against DT104 are limited and/or the system started to be overrun by the high numbers of DT104.

Gastric acids in the stomach (or abomasum) are the next line of host defense, which *Salmonella* must overcome during gastrointestinal passage [118]. Like most enteric pathogens, *Salmonella enterica* is well adapted to the acid conditions of the stomach [119]. Our experiments confirmed that acid adaptation with HCl at pH 5.5 lead to much higher survival rates at pH 3.5. Well-known mechanisms such as decreased membrane conductivity for H$^+$, increased proton extrusion or changes in the cell envelope composition [120-122] could be responsible for this.

Upon leaving the stomach, enteric pathogens are confronted with bile. Bile salts show antimicrobial activity by dissolving membrane lipids, dissociating integral membrane proteins [123], and lead to general cell damage by misfolding and denaturation of proteins [124, 125] and DNA damage [126, 127]. *Salmonella enterica* is able to survive duodenal bile salt concentrations through DNA repair mechanisms [127], multiple changes in gene expression [128], and increased production of anti-oxidative enzymes [129]. Here, selected DT104 strains were able to survive at both tested bile salt concentrations (14.5 mmol/L and 26.0 mmol/L); however, no
significant differences were observed between strains that harbored Gifsy-1/artAB/gogB and those that did not (Figure 5).

In summary, all tested strains were able to adapt to and survive in the in vitro gastrointestinal conditions tested here, while the presence or absence of Gifsy-1/artAB/gogB showed no fitness effects (Figure 5). However, it is important to note that we have only tested the most obvious stress conditions associated with the gastrointestinal tract; thus, it is conceivable that Gifsy-1/artAB/gogB loss among members of the U.S. artAB-negative major clade confer an advantage in conditions associated with the infection chain that were not tested here, including interactions with different host cell types.

**Future research is needed to understand the roles that Gifsy-1, ArtAB, and GogB play in DT104 virulence.** The results presented here indicate that prophage-mediated ArtAB production among DT104 can undergo temporal changes. Most notably, we identified the U.S. artAB-negative major clade, the common ancestor of which lost the ability to produce ArtAB in close temporal proximity to the global MDR DT104 epidemic. However, the ecological and/or evolutionary significance of this loss-of-function event remains unclear. Although phenotypic assessments have demonstrated a role for DT104-encoded ArtAB in both cell culture and a mouse model [18], the true benefit of this toxin in the context of human and bovine salmonellosis has not been investigated. It has been previously shown that reactive oxygen species (ROS) induce production of ArtAB [23], which may suggest that artAB is expressed in response to immune cell derived ROS. Furthermore, as treatment with ArtA increases intracellular levels of cAMP in macrophage-like cells [18], ArtAB may play a role in delaying *Salmonella* clearance by altering the activity of host immune cells [19]. Hence, future studies,
including in tissue culture and animal models, will be needed to determine whether \textit{artAB}

presence or absence confers a selective advantage among human- and animal-associated DT104.

The \textit{in vitro} stress assays performed in this study aimed to mimic the stressors that

DT104 encounters in the gastrointestinal tracts of humans and ruminants. Given the over-

representation of human-associated Gifsy-1/\textit{artAB}/\textit{gogB}-negative strains observed here, one may

be tempted to speculate that Gifsy-1, \textit{artAB}, and/or \textit{gogB} absence may confer members of the

U.S. \textit{artAB}-negative major clade with a competitive advantage in the human host gastrointestinal

tract; however, no Gifsy-1/\textit{artAB}/\textit{gogB}-dependent phenotype of DT104 was observed under the

tested conditions (Figure 5). Despite this, it may be possible that Gifsy-1/\textit{artAB}/\textit{gogB} absence

may confer some advantage(s) to U.S. \textit{artAB}-negative major clade strains in environmental

conditions, which were not tested in this study, including those outside of the host (e.g., high

osmotic pressure and competitive microbiota in manure or wastewater, food safety measures like

disinfectants, antimicrobials and food processing) [111]. However, at the present, this is merely

speculation; future studies are needed to evaluate whether Gifsy-1/\textit{artAB}/\textit{gogB} loss among

members of the U.S. \textit{artAB}-negative major clade is merely coincidental or indicative of some

evolutionarily advantageous phenotype.

<sup>a</sup> Identified using nucleotide BLAST (blastn; default settings, with no minimum identity or coverage threshold employed).

<sup>b</sup> Identified using the PHASTER webserver; Gifsy-1 regions annotated as “intact”, “incomplete” or “questionable” were considered to be “present” in a genome.

<sup>c</sup> Refers to the set of 219 U.S. human- and bovine-associated DT104 genomes acquired as described previously [24] and characterized here, plus 11 bovine- and human-associated U.S. DT104 genomes from the global DT104 data set.

<sup>d</sup> Refers to a set of 243 Scottish human- and bovine-associated DT104 genomes sequenced and characterized previously [36].

<sup>e</sup> Refers to a set of 290 DT104 genomes collected from various sources around the world, which were sequenced and characterized previously [13].
Table 2. Location of *artAB* and *gogB* in DT104 genomes within the U.S., Scottish, and global DT104 data sets, plus all data sets combined.

a Identified using nucleotide BLAST (blastn; default settings, with no minimum identity or coverage threshold employed).
b Identified using the PHASTER webserver; “intact” refers to prophage classified by PHASTER as “intact”, while “incomplete” encompasses prophage classified as “incomplete” or “questionable”.
c Percentages in parentheses were calculated relative to the “# of genomes with gene” value in the “Data Set” column used as a denominator.
e Refers to a set of 243 Scottish human- and bovine-associated DT104 genomes sequenced and characterized previously [36].
f Refers to a set of 290 DT104 genomes collected from various sources around the world, which were sequenced and characterized previously [13].
FIGURES

Figure 1. Geographic and source origins (i.e., human or bovine) of (A) all 230 human- and bovine-associated United States (U.S.) DT104 genomes queried in this study, and (B) 42 Gifsy-1/artAB/gogB-negative genomes assigned to the U.S. artAB-negative major clade. U.S. states shown in gray did not contribute any genomes to the respective data set. The U.S. state that contributed the most genomes to its respective data set is labeled. The figure was created using BioRender (https://biorender.com/) and the “plot_usmap” function in the usmap version 0.6.0 R package [130].

Figure 2. Bayesian time-scaled phylogeny constructed using 146 human- and bovine-associated DT104 genomes collected in the United States (U.S.). Tip label colors denote the isolation source reported for each genome (human or bovine in pink and blue, respectively). The heatmap to the right of the phylogeny denotes the presence and absence of (i) selected virulence factors (dark and light pink, respectively) and (ii) prophage (dark and light green, respectively). The U.S. artAB-negative major clade is denoted by the bright purple bar; light purple shading around the node of the U.S. artAB-negative major clade denotes the 95% highest posterior density (HPD) interval, in which Gifsy-1/artAB/gogB were predicted to have been lost. The phylogeny was constructed and rooted using BEAST2. Time in years is plotted along the X-axis, while branch labels correspond to posterior probabilities of branch support (selected for readability). For extended versions of this figure, see Supplementary Figures S2-S4.
**Figure 3.** Coalescent Bayesian Skyline plot constructed using 146 U.S. bovine- and human-associated *S. Typhimurium* DT104 genomes. Effective population size and time in years are plotted along the Y- and X-axes, respectively. The median effective population size estimate is denoted by the solid black line, with upper and lower 95% highest posterior density (HPD) interval bounds denoted by gray shading. The interval shaded in light blue and bounded by dashed vertical lines denotes the time interval in which Gifsy-1/*artAB*/gogB were predicted to have been lost by the common ancestor of the U.S. *artAB*-negative major clade (corresponding to the years 1985.0 and 1987.2, denoted by turquoise and pink dashed lines, respectively). The dotted turquoise and pink vertical lines correspond to the 95% HPD interval lower and upper bounds for Gifsy-1/*artAB*/gogB loss among members of the U.S. *artAB*-negative major clade (corresponding to the years 1979.0 and 1992.1, respectively).

**Figure 4.** Time-scaled maximum likelihood (ML) phylogeny constructed using the combined 752-genome DT104 data set. Tip label colors denote the study with which each genome is affiliated. The heatmap encompassing the phylogeny denotes the presence and absence of selected virulence factors and intact prophage. The ML phylogeny was constructed using IQ-TREE and rooted and time-scaled using LSD2. Branch lengths are reported in years. For an extended version of this figure, see Supplementary Figure S9.
Figure 5. Response of DT104 isolates (n = 6) to environmental stress factors correlated with the presence of Gifsy-1/artAB/gogB. Base-ten logarithmic fold change (FC) was calculated as follows: $\text{FC} = \log \text{CFU/g at the start of the experiments} - \log \text{CFU/g after the stress assay}$. (A) Log FC of DT104 inoculated into ruminal fluid at high ($10^8$ CFU/mL; “High”) or low ($10^5$ CFU/mL; “Low”) bacterial numbers. (B) Log FC of DT104 isolates exposed to inorganic acid stress (pH 3.5) with or without a prior adaption step with an intermediate pH (pH 5.5). (C) Log FC of DT104 isolates after exposure to bile salt at two concentrations.
Figure 1. Geographic and source origins (i.e., human or bovine) of (A) all 230 United States (U.S.) DT104 genomes queried in this study, and (B) 42 Gifsy-1/artAB/gogB-negative genomes assigned to the U.S. artAB-negative major clade. U.S. states shown in gray did not contribute any genomes to the respective data set. The U.S. state that contributed the most genomes to its respective data set is labeled.
