

1 Supplementary Material

2 Germination Experiment

3 Methods

4 For each of 8 incubation times (0, 10, 12, 16, 20, 24, 48, and 72 h post-exposure), 5
6 *Reticulitermes flavipes* workers from the same colony (Colony F; collected in Soulac-sur-Mer,
7 France in 2015; maintained in opaque plastic boxes containing damp soil and wood at 26°C,
8 84% humidity in the dark) were chilled in a plastic Petri dish on ice, then individually
9 immersed in 15µL drops of a 1×10^8 conidia/mL *Metarhizium anisopliae* suspension pipetted
10 directly on top of them. The termites were placed on a dry cellulose pad to absorb excess
11 liquid, then transferred to individual wells of a six well plate, each containing one quarter of a
12 Pall cellulose pad moistened with 300 µL water. The plates were incubated at 27°C under
13 low light conditions in a box with wet paper towels to keep humidity high. An equivalent
14 number of controls were briefly immersed in 0.05% Tween 80 and incubated individually
15 under the same conditions.

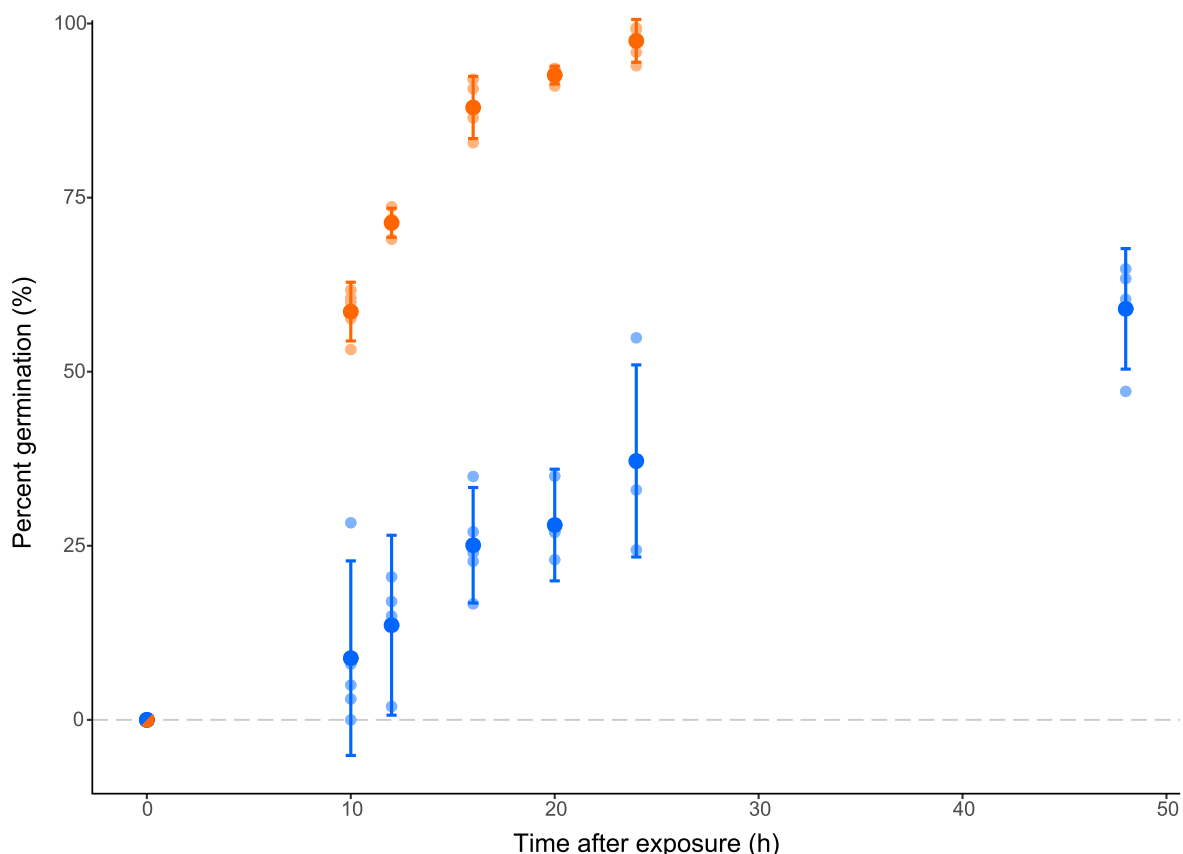

16 At each time point, *M. anisopliae*-exposed termites were preserved in 70% ethanol. After all
17 had been preserved in this manner, the termites were dehydrated in increasing ethanol
18 concentrations (30 min 90% ethanol, 2x 30 min 100% ethanol, 2x 30 min anhydrous 100%
19 ethanol), critical point dried using CO₂ (12 medium changes; CPD 030, BALTEC, Balzers,
20 Liechtenstein), sputtered with gold in a SCD 040 (Balzers, Liechtenstein), and then imaged
21 with a scanning electron microscope (SEM; FEI Quanta 200, FEI Deutschland GmbH,
22 Frankfurt/Main, Germany). The germination rate was calculated by evaluating at least 100
23 conidia on the termite head according to the following criteria: a conidium was considered
24 germinated if the germ tube was longer than half the diameter of the conidium. Two termites,
25 one in the 12 h incubation group and one in the 20 h incubation group, were excluded from
26 further analysis because they had too few conidia adhering to their cuticles to calculate a
27 germination rate. After 48 h, it was no longer possible to evaluate germination due to dense
28 fungal and bacterial growth on the termite cuticle (Figure S2).

29 To evaluate germination in vitro, 5 PDA plates were streaked with the same conidial
30 suspension, parafilm, and incubated at 27°C under low light. At 0, 10, 12, 16, 20, and 24 h
31 after inoculation, at least 100 conidia per plate were evaluated for germination at 200-400x
32 using a phase contrast microscope. After 24 h, dense hyphal growth made it impossible to
33 calculate a germinate rate.

Means and 95% confidence intervals were calculated and plotted using R (version 3.4.3) [1].

34 Results

35 Germination was first observed at 10 hours (Figure S1, Figure S3); the earliest time reported
36 in the literature is 12 hours after exposure [2, 3]. In vitro, under ideal conditions, germination
37 can begin as early as 5 hours after inoculation [4], but it is known to be delayed on arthropod
38 cuticles [5].

39
40 Figure S1. Germination on PDA plates (orange; the steeper curve) and *Reticulitermes flavipes* worker cuticles (blue). Larger dots
41 represent means, smaller dots are individual data points, and bars show 95% confidence intervals.

42
43 We observed *M. anisopliae*-treated termites showing signs of illness (moribund; when
44 grabbed with forceps, they would bite rather than try to run) as early as 15 hours after
45 exposure to the conidial suspension. The timing of this behavioural change, which correlates
46 with the presence of an internal infection [3] and is consistent with an older high dose study
47 in which moribundity was observed at 16 hours [6], indicates that penetration must begin
48 shortly after germination. Our results contrast with prior fungal life cycle studies which report
49 that penetration occurs 24-36 hours after exposure [3]. The discrepancy may be the result of
50 difficulty spotting penetration: when reviewing SEM images, we were unable to reliably
51 distinguish between germ tubes that had or had not penetrated. Appressoria were
52 occasionally observed at 12 hours after exposure (Figure S4), but as the infection peg, if

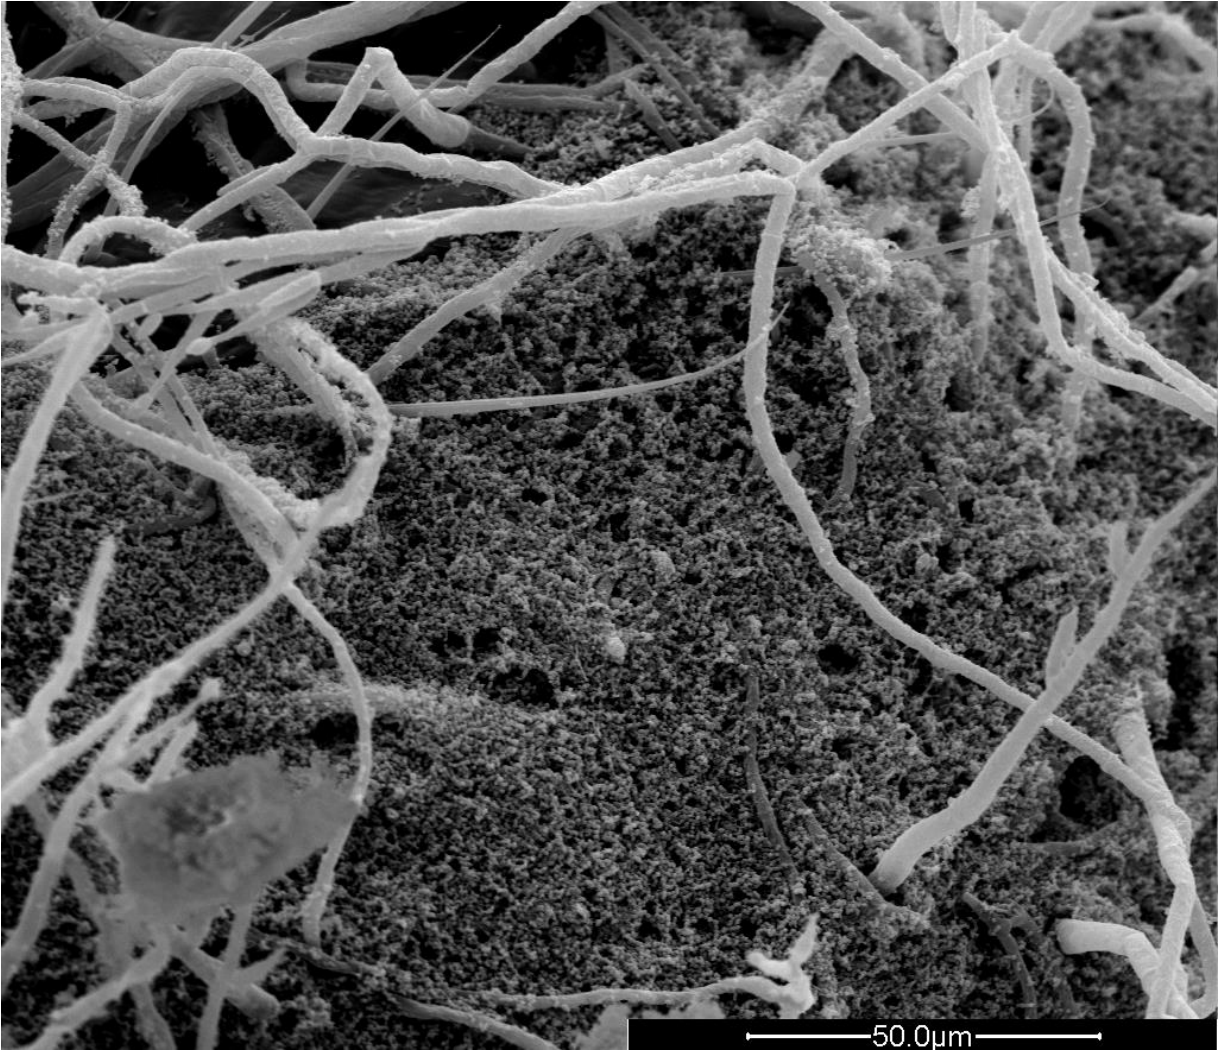

53 present, would be underneath the appressorium and hidden from view, we could not say
54 whether penetration had already begun.

55 At 20 hours, the termites were still alive, but very lethargic. Death occurred between 24 and
56 48 hours. Germination on the cuticle, which was consistently lower than germination on PDA,
57 continued even after the termite's death from the infection, as did hyphal growth (Figure S5).
58 All controls, with the exception of one that died from an apparent handling injury, were alive
59 and healthy 1 week after the beginning of the experiment.
