ABSTRACT

Inter-individual variation in metabolic health and adiposity is driven by many factors. 23 Diet composition and genetic background and the interactions between these two 24 25 factors affect adiposity and related traits such as circulating cholesterol levels. In this study, we fed 850 Diversity Outbred mice, half females and half males, with either a 26 standard chow diet or a high fat, high sucrose diet beginning at weaning and aged them 27 to 26 weeks. We measured clinical chemistry and body composition at early and late 28 time points during the study, and liver transcription at euthanasia. Males weighed more 29 than females and mice on a high fat diet generally weighed more than those on chow. 30 Many traits showed sex- or diet-specific changes as well as more complex sex by diet 31 interactions. We mapped both the physiological and molecular traits and found that the 32 genetic architecture of the physiological traits is complex, with many single locus 33 associations potentially being driven by more than one polymorphism. For liver 34 transcription, we find that local polymorphisms affect constitutive and sex-specific 35 transcription, but that the response to diet is not affected by local polymorphisms. We 36 identified two loci for circulating cholesterol levels. We performed mediation analysis by 37 mapping the physiological traits, given liver transcript abundance and propose several 38 genes that may be modifiers of the physiological traits. By including both physiological 39 and molecular traits in our analyses, we have created deeper phenotypic profiles to 40 41 identify additional significant contributors to complex metabolic outcomes such as polygenic obesity. We make the phenotype, liver transcript and genotype data publicly 42 available as a resource for the research community. 43

INTRODUCTION

47

Many factors affect the physiology and transcriptional landscape of individuals. Intrinsic 48 factors, such as sex and genetic background, play a role in shaping individuals. External 49 50 factors, such as diet and other environmental stimuli, also play a role in determining the health and well-being of each person. However, wide variation in individual response to 51 diet is an enormous challenge to developing prevention and treatment strategies aimed 52 53 at reducing the incidence of obesity and metabolic disorders. The response to diet is 54 affected by both sex (GRIFFIN et al. 2016) and individual genetic background (SUHRE and GIEGER 2012). Disparity in obesity prevalence among sexes has been ascribed to 55 both biological and sociocultural factors (KANTER and CABALLERO 2012). Sex differences 56 in fat gain and storage can lead to considerable differences in health outcome among 57 women and men (POWER and SCHULKIN 2008). Additionally, sex-dependent single 58 59 nucleotide variants have been reported that underlie differential contributions to the development of obesity (KVALOY et al. 2013; SALDANA-ALVAREZ et al. 2016). 60

61

In human populations, it is difficult to dissect the genetic basis for differential responses to diet between the sexes due to differences in lifestyle and uncontrolled covariates. While epidemiological models can estimate correlations between different traits, the controlled conditions in mouse models allow us to apply randomization and factorial designs to detect causal associations between obesity and physiological traits. In mouse models, we can also control the genetic background of the mice, thereby

reducing another uncontrolled variable that influences the response to diets between the sexes. Most mouse models of obesity use a single inbred strain genetically engineered or experimentally manipulated to become obese (reviewed in (HARIRI and THIBAULT 2010)). However, genetic background is known to influence the response of individuals to dietary fat (WANG *et al.* 2002; STOEHR *et al.* 2004; SU *et al.* 2008; LIN *et al.* 2013). In order to generalize our results from mice to humans, it is critical to include structured genetic diversity in mouse models of dietary response.

75

Multi-parent advanced intercross (MAGIC) populations are powerful models for mapping 76 77 genetic modifiers of complex traits due to their high minor allele frequency and fine mapping resolution (CHURCHILL et al. 2004; RAKSHIT et al. 2012; RAT GENOME et al. 78 2013; GATTI et al. 2014). In MAGIC populations derived from known founders, the 79 haplotype structure of each sample genome can be reconstructed in terms of the 80 founder genomes (MOTT et al. 2000; GATTI et al. 2014). When the founders have been 81 fully sequenced, the founder sequences can be imputed onto the MAGIC genomes to 82 allow for whole genome association mapping (YALCIN et al. 2005), which improves the 83 ability to identify candidate genes that influence traits. Transcript profiling in a relevant 84 tissue adds another important dimension to genetic mapping studies and can be used to 85 perform mediation analysis on each significant genomic locus (CHICK et al. 2016). 86 87 There are several mouse MAGIC populations available, including the Northport Heterogeneous Stock (VALDAR et al. 2006), the Collaborative Cross (THREADGILL and 88 CHURCHILL 2012), the Heterogeneous Stock/Collaborative Cross (IANCU et al. 2010) and 89 90 the Diversity Outbred (SVENSON et al. 2012).

92	In this study, we fed Diversity Outbred mice of both sexes either standard chow or a
93	high-fat/high-sucrose diet from weaning until approximately 6 months of age. We
94	measured a variety of physiological traits throughout the study and performed liver
95	transcriptional profiling at the end of the study. Here, we report on the differential effects
96	of diet on each sex in terms of physiological and transcriptional trait, provide interactive
97	viewers for the results and release the entire data set to the public through
98	supplemental materials and at http://do.jax.org.
99	
100	METHODS
101	
102	Mice and husbandry: Diversity Outbred mice were obtained from The Jackson
103	Laboratory (Bar Harbor, ME). This study used five independent cohorts of 100-200 non-
104	sibling DO mice from generations 4 to 11 (G4-G11) for a total of 850 animals, which
105	builds on an initial study that has previously been reported (SVENSON et al. 2012). In
106	each cohort, half the animals were from first litters in the respective generation and half
107	were from second litters. An equal number of females and males were included in each
108	set of animals received. Mice were housed at a density of five same-sex mice per pen in
109	pressurized, individually ventilated cages (Thoren #11 Duplex II; Thoren Caging
110	Systems, Hazelton, PA) with pine bedding (Crobb Box, Ellsworth, ME) and free access
111	to food (diets described below) and acidified water. Light cycle was 12h:12h light:dark,
112	beginning at 0600. All animal procedures were approved by the Animal Care and Use
113	Committee at The Jackson Laboratory (Animal Use Summary # 06006).

Phenotyping: Upon receipt, when mice were 3 weeks of age, equal numbers of each 115 sex were randomly assigned to chow (LabDiet 5K52, LabDiet, Scott Distributing, 116 117 Hudson, NH) or high fat, high sucrose feeding (Envigo Teklad TD.08811, Envigo, Madison, WI) for the duration of the study protocol (26 weeks). Caloric content of the 118 high fat diet (HFD) was 45% fat, 40% carbohydrates and 15% protein. Tail biopsies 119 were taken at wean for DNA preparation. Weight was monitored weekly throughout the 120 study. At age 8 weeks mice began a pipeline of noninvasive phenotyping assays to 121 profile metabolic health (Table 1). Some modifications to the pipeline were made as the 122 number of cohorts progressed, such that all parameters were not measured in all mice. 123 Table 1 lists each phenotypic measurement and the number of mice tested. Data was 124 125 obtained from 846 mice and 154 traits were used for analysis. Clinical chemistries, urinalysis and body composition assessments were performed at two time points in the 126 study to evaluate stability of traits under prolonged HFD. Hence, calculated traits 127 128 comparing first and second measures were generated as derived traits. Details about blood collection and analysis and body composition by dual-energy x-ray 129 absorptiometry (DEXA) have been described previously for this pipeline (Svenson 2012 130 Genetics). Additional tests include body composition by qNMR (EchoMRI), 131 electrocardiogram, intraperitoneal glucose tolerance test (ipGTT), and evaluation of 132 chemokines by electrochemiluminescence. To quantitate lean and fat tissue and free 133 and total water, EchoMRI (EchoMRI, Houston, TX) without anesthesia was used, 134 providing three time points for evaluation of tissue composition during the study and 135 136 minimizing the need for anesthesia during the pipeline. Electrocardiography was

performed using the ECGenie[™] (Mouse Specifics, Quincy, MA) system, whereby 137 unanesthetized mice are placed on a platform raised 18" above the laboratory bench 138 containing a lead plate. When animals contact the plate with any three paws the trace 139 140 begins. Fast Fourier analysis (AnonyMouse[™] software v2.2; Mouse Specifics) defines interval durations from which heart rate, variability and other features of cardiac 141 conduction can be assessed. To evaluate glucose clearance, mice were fasted 142 overnight (15 hours) and in the morning mice were weighed and a small blood sample 143 from a tail tip incision was used in the Abbott glucometer system to measure fasted 144 glucose (GTT time 0; t0). A glucose solution was then injected intraperitoneally at 2 mg 145 glucose/gram body weight and tail tip blood samples were obtained at 15, 30, 60, 120 146 and 180 minutes after injection. Plasma leptin, insulin, ghrelin and adiponectin were 147 measured from nonfasted mice using the Meso Scale Discovery™ 148 electrochemiluminescent assay detection system according to the manufacturer's 149 protocols. We transformed all traits to ranked Z-scores before performing statistical 150 151 analyses.

152

Genotyping and Diplotype Reconstruction: DNA was prepared from tail biopsies and genotyped using two versions of the Mouse Universal Genotyping Array (MUGA) (MORGAN *et al.* 2016). We genotyped 531 samples on the MUGA and 293 samples on the Megamuga (GeneSeek, Lincoln, NE). We used the intensities from each array to infer the haplotype blocks in each DO genome using a hidden Markov model (HMM) (GATTI *et al.* 2014).

159

160 Genotyping by RNA-sequence: Genotyping by RNA-sequence (GBRS) is a set of software tools that reconstruct individual genomes of each sample in multi-parent 161 population (MPP) models by decoding known polymorphisms of founder strains from 162 163 RNA-Seg data without resorting to genotyping arrays. The new method is efficient since it avoids maintaining hundreds of individualized genome indexes by aligning RNA-Seq 164 reads to a common pooled transcriptome of all founder strains a single time. Since our 165 reusable model parameters can be easily estimated from separate RNA-Seg data of 166 inbred founder strains or from simulations, we can quickly process each MPP sample 167 independently. The software package implements our alignment strategy and statistical 168 169 models and is freely available at https://github.com/churchill-lab/gbrs. We used the GBRS haplotype reconstructions to fill in samples that failed to genotype due to low call 170 171 rates on the MUGA or Megamuga.

172

Merging Haplotype Reconstructions from Different Methods: The MUGA and Megamuga have different numbers of markers (MUGA: 7,854, Megamuga: 77,642) and the HMM produced diplotype probabilities only at each marker. In contrast, the GBRS method produced diplotype probabilities at each gene that was expressed in the liver. In order to merge diplotype probabilities from the data, we interpolated both markers grids to an evenly spaced 64,000 marker grid (0.0238 cM between markers). After merging the diplotype reconstructions, we had a total of 835 samples.

180

Principal Component Analysis of Physiological Traits and Liver Transcription: We
 retained 129 out of 160 physiological traits with < 50% missing data across samples.

The 24 traits with > 50% missing data were ACR1, ACR2, Adiponectin, BW.3, BW.27, BW.28, BW.29, BW.30, fat.g.mri, free.h20, FRUC1, Ghrelin, GTT.AUC, GTT.t0, GTT.t15, GTT.t30, GTT.t60, GTT.120, GTT.180, Lipase1, non.fast.Calcium, TBIL1, TBIL2 and tot.h20 (see File S1 for abbreviations). We used the Probabilistic PCA method of the pcaMethods software (STACKLIES *et al.* 2007) to impute missing data in the remaining traits and calculated the first 10 principal components.

189

Physiological Traits Correlations: We regressed out the outbreeding generation, sex
 and diet effects from each of the physiological traits and calculated the pairwise
 Pearson correlation between all physiological traits.

193

194 Alignment, Quantification and Normalization of Liver Transcription Data: We aligned reads from the DO liver data to pooled transcriptomes derived from the eight 195 DO founder strains by incorporating strain-specific SNPs, insertions and deletions into 196 197 the reference genome sequence. We quantified expected read counts using an expectation maximization algorithm (EMASE, https://github.com/churchill-lab/emase) 198 (CHICK et al. 2016). We retained 12,067 genes with mean transcripts per million across 199 200 all samples greater than one. We normalized effective counts to the upper quartile value and transformed them to rank normal scores. 201

202

203 Differential Expression and Gene Set Enrichment Analysis of Liver Transcript 204 Data:

We performed analysis of variance (ANOVA) on the normalized liver transcription data to identify genes that were differentially expressed between sexes, diets or that had a sex by diet interaction. We regressed the expression of each gene on generation and litter, sex, diet and the sex by diet interaction. We adjusted the p-values using the Benjamini & Hochberg false discovery rate (FDR)(BENJAMINI and HOCHBERG 1995).

210

We searched for Gene Ontology (GO) categories (ASHBURNER et al. 2000) that were 211 212 differentially expressed between sexes, diets or that had a sex by diet interaction using the SAFE software package (BARRY et al. 2005). We used the "t.Student" local statistic 213 to test for differential expression for each gene and the "Wilcoxon" global statistic to test 214 for differential enrichment between categories. For sex effects, we regressed diet from 215 216 each gene and then tested for the effect of sex. For diet effects, we regressed sex from 217 each gene and then tested for the effect of diet. For the sex by diet interaction, we compared the reduced model with sex and diet to the full model containing sex, diet and 218 219 the sex by diet interaction. We determined the empirical p-value for each category using 10,000 permutations and retained GO categories with p-values ≤ 0.05 . 220

221

Linkage Mapping: At each marker, we regressed each phenotype on generation, sex, diet and the diplotype probabilities for each mouse and included an adjustment for correlation between residuals due to kinship. We used the same model for liver expression QTL mapping. We performed 5,000 permutations of a rankZ transformed phenotype and selected significance thresholds from the empirical distribution of maximum LOD scores. We estimated the founder allele effects using a Best Linear

Unbiased Predictor (BLUP) in which we fit a mixed-effects model at each marker that shrinks the founder effects in proportion to the magnitude of the standard errors. We used the *qtl2* R package available at: <u>https://github.com/rqtl</u>. Full details of the linkage mapping model are in (GATTI *et al.* 2014).

232

Association Mapping: We imputed the DO founder SNPs from the Sanger Mouse Genomes Project (REL-1505) onto each founder haplotype block in the DO genomes. We then regressed each phenotype on generation, sex, diet and the SNP probabilities for each mouse and included an adjustment for correlation between residuals due to kinship. Full details of the association mapping model are in (GATTI et al. 2014).

238

239 Mediation Analysis: For each physiological QTL peak with a genome-wide adjusted p-240 value above 0.05, we performed mediation analysis to identify candidate liver genes that might be responsible for the peak (CHICK et al. 2016). We fit a null model by 241 242 regressing the phenotype on generation, sex, diet and the diplotype probabilities at the markers with the maximum LOD score. We added the expression of each of the 12,067 243 genes to the model and recorded the drop in the LOD score compared to the null 244 245 model. We estimated the standard deviation of the LOD drops and report genes that decreased the LOD score by more than 6 standard deviations. We refer to these 246 standardized LOD score drops as "Z-scores". We used the intermediate R package 247 available at https://github.com/simecek/intermediate . 248

249

Data and Reagent Availability: J:DO mice are available for purchase from The 250 Jackson Laboratory (Strain # 009376) at https://www.jax.org/strain/009376. The liver 251 gene expression data is archived at the Short Read Archive under project number 252 253 PRJNA35625. The physiological phenotypes are described in File S1, the raw phenotypes are in File S2 and the normalized phenotypes are in File S3. The genotype 254 data for all mice and the R data objects used in all analyses are available at 255 256 http://do.jax.org. We used the Sanger REL-1505 SNPs and structural variants (KEANE et al. 2011) and the Ensembl build 82 transcripts (YATES et al. 2016). 257

RESULTS

260

Impact of Sex and Diet on Physiological Traits and Liver Transcription

262

We maintained mice of both sexes on either a chow diet (n = 449) or a high fat diet (n = 449)263 397) from wean to at least 26 weeks. We measured a range of physiological traits 264 throughout the study and measured several traits at two time points (File S1). We 265 calculated the principal components of the physiological traits and found that the mice 266 grouped by sex and diet (Figure 1A). Principal component (PC) 1 accounted for 29.2% 267 of the variance and is correlated with sex. PC2 accounts for 7.6% of the variance and is 268 correlated with diet. We also quantified liver transcription at 26 weeks in a subset of 478 269 270 mice. When we calculated the PCs for a subset of 12,067 genes, we found that the samples also clustered by sex and diet (Figure 1B). PC1 and 2 accounted for 12.1% 271 and 10.9% of the variance, respectively. Mice on the chow diet formed tighter clusters 272 273 than mice on the high fat diet, reflecting larger variance in liver gene expression in mice on the high fat diet. 274

275

276 **Correlation between Physiological Traits:** We calculated the pairwise Pearson 277 correlation of all traits after regressing out sex and diet and identified several clusters of 278 correlated traits (File S4). Most traits measured at two time points clustered near each 279 other, indicating that genetic background affects many traits throughout the mouse's 280 lifespan. Body weight (BW) at all time points was positively correlated with other BW as 281 well as adiponectin, insulin, bone mineral density (BMD) and lean and fat tissue mass.

Cholesterol (CHOL) at 19 weeks was highly correlated with high-density lipoprotein 282 (HDLD, $\rho = 0.95$, p < 10⁻¹⁶), as expected for mice, triglycerides (TG, $\rho = 0.40$, p < 10⁻¹⁶), 283 glucose ($\rho = 0.28$, $p = 1.7 \times 10^{-16}$), non-esterified fatty acids (NEFA, $\rho = 0.44$, $p < 10^{-16}$), 284 body weight ($\rho = 0.20$, p < 6.6 x 10⁻⁹) and circulating calcium (Ca, r = 0.50, p < 10⁻¹⁶). 285 These correlations are in agreement with recent evidence that circulating calcium levels 286 are associated with worsening lipid profiles in humans (GALLO et al. 2016) and that 287 coronary artery calcification is an independent risk factor for atherosclerosis and 288 289 cardiovascular disease (BUDOFF et al. 2007). The area under the curve of the glucose tolerance test at 24 weeks (GTT) was positively correlated with BW at 24 weeks (ρ = 290 0.29, p = 4.70 x 10⁻⁵) and other time points, GLUC at 19 weeks ($\rho = 0.30$, p = 1.87 x 10⁻⁵) 291 ⁶), leptin at 8 weeks ($\rho = 0.21$, $p = 2.62 \times 10^{-3}$), indicating a connection between appetite 292 and circulating glucose levels. Leptin ($\rho = 0.80$, p < 10⁻¹⁶), insulin ($\rho = 0.42$, p < 10⁻¹⁶), 293 adiponectin ($\rho = 0.40$, p < 10⁻¹⁶) and % fat at both time points were positively correlated, 294 indicating a connection between appetite and adiposity. Glutamate dehydrogenase 295 (GLDH) at 19 weeks was positively correlated with and BW traits at ages over 15 weeks 296 $(\rho = 0.212, p = 2.45 \times 10^{-9})$. While this observation may suggest that liver injury is 297 associated with increased weight, it is not correlated with increased fat tissue mass as 298 might be expected. It is likely that this correlation is an effect of aging and may be driven 299 by those animals that were fed HFD. The correlations are available as an interactive on-300 line tool at: http://churchill-lab.jax.org/www/Svenson850/corr.html. 301

302

Impact of Sex and Diet on Physiological Traits: We tested each trait for the effect of
 sex, diet and a sex by diet interaction in order to identify the effects of each on the

305 physiological traits (File S5). This analysis stratified our results into four effect classes, each demonstrated by examples in Figure 2. There were 12 traits for which no 306 difference was found between sexes or diet groups, including eosinophil counts (EOS) 307 and spleen weight (Figure 2A). Sex had an effect on 130 traits at a false discovery rate 308 (FDR) \leq 0.05 (Figure 2B). Males had higher mean values for 101 of these traits, 309 including body weight, monocyte counts (MONO), neutrophil counts (NEUT), glucose 310 tolerance test (GTT.AUC), heart rate (HR), mean corpuscular volume (MCV), mean 311 platelet volume (MPV), phosphorous, platelet counts (PLT), red blood cell distribution 312 width (RDW) and cholesterol (CHOL). Females had higher mean values for 29 traits, 313 including mean corpuscular hemoglobin concentration (CHCM), hemoglobin (HGB), 314 ghrelin, %Fat and red blood cell counts (RBC). 315

316

Diet had an effect on 116 traits at an FDR \leq 0.05. Mice on the HFD had higher mean traits values for adiponectin, weight and fat traits, %Fat, GTT.AUC, HGB, insulin, leptin, total bilirubin (TBIL), glutamate dehydrogenase (GLDH) and CHOL. Mice on the chow diet had higher blood urea nitrogen (BUN), kidney weight, MONO, NEUT, PLT, triglycerides (TG) and urine creatinine and glucose.

322

CHOL was higher in males as compared to females at both time points and on both diets (File S5). At eight weeks, males on the chow diet (94.1 mg/dL) had CHOL levels higher than females (78.4 mg/dL). At 19 weeks, CHOL levels on the chow diet were similar to levels at eight weeks in males (94.2 mg/dL) and females (75.8 mg/dL). The HFD increased CHOL levels at both time points. At eight weeks, males on the HFD

328 (126 mg/dL) had CHOL levels that were 20% higher than females (105 mg/dL). At 19 weeks, males (128 mg/dL) had CHOL levels that were 16.3% higher than females (110 329 mg/dL) (Figure 2C). At 19 weeks, the HFD increased CHOL by 45.1% compared to the 330 chow diet in females and by 35.9% in males. CHOL levels did not change greatly 331 between eight and 19 weeks. Female CHOL levels on the HFD increased by 4.7% from 332 105 mg/dL to 110 mg/dL and males increased by 1.6% from 126 mg/dL to 128 mg/dL. 333 Therefore, the increase in CHOL levels compared to chow values was established by 334 eight weeks in the HFD group and increased only minimally by the second time point. 335

336

There were 14 traits for which sex and diet showed a significant interaction (FDR \leq 0.05, Figure 2D). BMD2 had one of the strongest sex by diet interactions, with mice on the chow diet having similar BMD between the sexes, but males having higher BMD than females on the HFD. This may be due to males gaining more weight and needing stronger bones to carry the weight. This is consistent with higher BW in males and the correlation of BW to BMD, such that male weight gain may require bone fortification to support increased body mass.

344

Impact of Sex and Diet on Liver Transcription: We tested each of the 12,067 transcripts for the effects of sex, diet and a sex by diet interaction (File S6). We found 7,723 genes with sex effects (FDR \leq 0.01) and 5,299 genes with significant diet effects (FDR \leq 0.01). We found 757 genes with a significant sex by diet interaction. In order to interpret the functional relevance of these large gene lists, we searched for Gene Ontology (GO) categories that were enriched in for each effect. We identified 212 GO

351 Biological Process (GO.BP) categories out of 2,570 in which genes were differentially expressed between the sexes ($p \le 0.05$, File S7). Of those traits affected by sex, organ 352 regeneration (GO:00031100) was the most significant category and was higher in 353 354 This was followed by lipid metabolism (GO:0006629) and transport males. (GO:0006869), which was higher in males. However, cholesterol metabolism 355 (GO:0008203, GO:0006695) was lower in males. Fatty acid metabolism (GO:0000038 & 356 GO:0070542) and beta-oxidation were higher in male mice along with catabolism of 357 358 triglycerides (GO:0019433). Of note, male mice had higher expression of genes involved in unfolded protein responses (GO:1900103, GO:0072321), extracellular matrix 359 360 disassembly (GO:0022617), and fibroblast proliferation (GO:0048146). This suggests that males experienced greater stress from unfolded protein responses, cellular 361 362 remodeling and proliferation.

363

We identified 212 GO.BP categories that contained genes that were differentially 364 365 expressed by diet ($p \le 0.05$, Supplemental File S11). For these, heat generation (GO:0031649) and energy reserve metabolism (GO:0006112) were upregulated in mice 366 on HFD. Lipid metabolism (GO:0045834) was upregulated while lipid biosynthesis 367 (GO:0051055), including fatty acids (GO:0006633, GO:0042761) and phospholipids 368 (GO:0008654, GO:0015914) was down-regulated in mice fed the HFD. Lipid storage 369 370 (GO:0010888), cholesterol transport (GO:0030301) and gluconeogenesis (GO:0045721) were all decreased in mice fed the HFD. Insulin secretion in response to 371 glucose stimulation was suppressed (GO:0061179) and glucose metabolism was 372 373 increased (GO:0010907). Overall, the HFD produced increases in lipid and energy

374 metabolism while decreasing lipid biosynthesis and storage, and perturbed glucose 375 homeostasis.

376

377 Physiological Trait Mapping

378

We mapped the physiological traits using each of three models: a model in which sex and diet were additive covariates (additive model); on in which sex and diet were additive covariates and sex interacted with genotype (sex-interactive model) and one in which sex and diet were additive covariates and diet interacted with genotype (dietinteractive model).

384

Additive Model: We identified 82 additive QTL with genome-wide p-values ≤ 0.05 (File S9). Of these, 39 were hematology traits, 23 were body weight or body composition traits, 14 were clinical chemistry traits, 3 were electrocardiogram traits and 3 were urinalysis traits.

389

Circulating cholesterol at 8 and 19 weeks (CHOL1 & CHOL2) had additive QTL on chromosome 1 at 171.37 Mb with a LOD of 13.92 for CHOL1 and 13.57 for CHOL2 (Figure 3A). The pattern of founder allele effects at this locus was similar at both time points (Figure 3B). The 129S1/SvImJ (129S1) and WSB/EiJ (WSB) alleles on the distal end of chromosome 1 were associated with higher cholesterol levels. We performed association mapping around the peak at 171.37 Mb and found that the most significant

396 SNPs (rs587286870 & rs580179709) had founder allele patterns for which the 129S1 and WSB strains carried the minor allele (Figure 3C). When we fit the association 397 mapping model again by including these SNPs as covariates, the maximum LOD score 398 399 in the region between 170 and 175 Mb decreased to 1.72, which is well below the significance threshold. Both rs587286870 and rs580179709 are in an intron of prefoldin 400 2 (Pfdn2), which is part of a molecular chaperone complex that stabilizes unfolded 401 proteins. It is unclear how Pfdn2 might impact circulating cholesterol levels. However, 402 we note that both of these SNPs are near a gene that is known to influence cholesterol 403 404 levels, apolipoprotein A-II (Apoa2) located at 171.2 Mb. The 129S1 strain carries a private alanine to valine substitution (rs8258226) that increases cholesterol levels 405 (WANG et al. 2004). The WSB strain carries a non-synonymous SNP (rs229811374) 406 that changes a serine to an asparagine and is located six nucleotides upstream of 407 rs8258226. If both of these SNPs increase cholesterol levels, this may explain the 408 increase in the 129S1 and WSB alleles effects at the Apoa2 locus (Figure 3D) and the 409 410 strong association with all SNPs where the minor allele occurs in both 129S1 and WSB. The peak in this region is broad and may include more than one locus and allele. When 411 we regressed out the effects of the 129S1 and WSB alleles at the Apoa2 locus, the 412 maximum LOD of 5.35 occurred at 138.178 Mb on chromosome 1. We searched for 413 other genes expressed in the liver that might influence cholesterol levels by mediating 414 415 the peak with the expression of each gene (see Methods). We found six genes that reduced the LOD score by greater than six standard deviations (i.e. had a Z-score < -6, 416 Figure 3E); inhibitor of kappaB kinase epsilon (*lkbke*), peptidase M20 domain containing 417 418 1 (*Pm20d1*), adenosine A1 receptor (*Adora1*), coagulation factor XIII, beta (*F13b*),

419 complement factor H-related 1 (Cfhr1) and cathepsin E (Ctse). Of these, Cfhr1 had a Zscore of -18.6, which was lower than any other gene. The next lowest Z-score was -13 420 for Ctse. We tested whether Ctse would still reduce the LOD score by performing 421 422 mediation analysis with Cfhr1 in the model and found that Ctse still had a Z-score of -9.6. We found that F13b had a Z-score of -6.7 in this scan as well. The founder allele 423 effects for Cfhr1 (Figure 3F) show that mice carrying the PWK/PhJ (PWK) allele have 424 higher Cfhr1 levels and mice carrying the A/J allele have lower levels. For Ctse, the 425 129S1, WSB and NZO/HILtJ (NZO) strains have higher *Ctse* expression (Figure 3G). 426 For F13b, the WSB allele is associated with lower F13b expression (Figure 3H). Cfhr1 427 is upregulated in the mouse retina in response to a different high fat diet (ZHENG et al. 428 2015). Ctse deficient mice fed a high fat diet showed hypercholesterolemia, reduced 429 body weight gain and impaired fat development compared to controls mice (KADOWAKI 430 et al. 2014). F13b is part of the coagulation cascade and has not been previously 431 associated with cholesterol metabolism. 432

433

We found a peak for CHOL2 on chromosome 5 at 123.760 Mb for which the NZO allele 434 was associated with higher cholesterol levels (Figure 4A). When we mediated the QTL 435 peak at 123.76 Mb with the liver expression of each gene on chromosome 5, we found 436 that TRAF-type zinc finger domain containing 1 (Trafd1) and scavenger receptor class 437 B1 (*Scarb1*) reduce the LOD score by more than six standard deviations (Figure 4B). 438 Trafd1 is associated with the regulation of innate immune responses and is not known 439 440 to have a function in cholesterol metabolism or transport. However, the pattern of allele effects (Figure 4C) and the mediation score suggest that it may play an unknown role. 441

442 We repeated the mediation scan using *Trafd1* expression as a covariate and found that Scarb1 was the only gene that reduced the LOD score by more than 6 standard 443 deviations. DO mice carrying the NZO allele at the QTL had lower transcript levels of 444 445 Scarb1 (Figure 4D), which is consistent with the founder allele effects for CHOL2. Scarb1 is the primary receptor for HDL-cholesterol uptake by the liver and steroidogenic 446 tissues and is vital for reverse cholesterol transport. Targeted mutations in Scarb1 lead 447 to abnormal lipoprotein metabolism and increased cholesterol levels (MOHR et al. 2004). 448 Liver-specific reduction in Scarb1 expression as a result of an ENU-induced point 449 450 mutation has also been reported, in which mice exhibit 70% higher plasma HDLcholesterol levels due to reduced HDL selective uptake (STYLIANOU et al. 2009). Scarb1 451 was proposed as a candidate gene for hypercholesterolemia in an intercross between 452 453 NZB/B1NJ and SM/J (PITMAN et al. 2002), but the authors found no sequence, mRNA or protein differences. However, whole-genome sequencing of NZO has revealed a stop 454 gain mutation (rs233349576, Figure 4E & F) at residue 37 in ENSMUST00000137783. 455 456 This may produce an incomplete protein and may alter its function.

457

QTL that Interact with Diet: There were 12 QTL with p-values ≤ 0.05 for which genotype interacted with diet (File S9), including 6 clinical chemistry traits, heart rate, lymphocyte counts, urinary creatinine, body weight and body length. Cholesterol at 8 weeks (CHOL1) had a QTL that interacted with diet on chromosome 10 at 21.99 Mb with a LOD of 10.6 (p ≤ 0.001 , Figure 5A). Mice carrying the NOD allele on the HFD had higher cholesterol levels. We mediated the QTL peak with all liver transcripts and found that *E030030106Rik* decreased the LOD by more than six standard deviations.

E030030106Rik has a local eQTL on chromosome 10 at the same location. Association mapping near the QTL peak produced significant associations with one gene, *Gm20125*, which is a gene model with no known function.

468

Heart rate at 13 weeks (HR) had a QTL that interacted with diet on chromosome 6 at 469 470 125.63 MB with a LOD of 10.4 ($p \le 0.001$, Figure 5B). Mice carrying the A/J or C57BL/6J allele on the HFD had higher HR than mice carrying the CAST allele. We did 471 not perform mediation analysis because we do not have heart transcript information on 472 473 these mice. Association mapping near the peak produced two SNPs (rs48596855, rs38346309) in the introns of anoctamin 2 (Ano2), a calcium activated chloride channel, 474 a class of genes that may play a role in cardiac function (GUO et al. 2008; HARTZELL et 475 al. 2009). Another gene, potassium voltage-gated channel, shaker-related 1, (Kcna1), is 476 located 1 Mb distal from the peak SNPs and has been associated with changes in heart 477 rate (GLASSCOCK et al. 2010). 478

479

Glutamate dehydrogenase, a marker of liver injury, at 19 weeks (GLDH2) had a QTL that interacted with diet on chromosome 9 at 92.19 Mb with a LOD of 11.86 ($p \le 0.001$, Figure 5C). Mice carrying the A/J, NZO or PWK alleles on the HFD had higher GLDH levels. There were no genes that had mediation Z-scores less than -6 near the QTL peak. When we performed association mapping near the peak, we found four transcripts with intronic SNPs and LOD scores over 7; *Gm29478*, *1700057G04Rik*, phospholipid scramblase 4 (*Plscr4*), and procollagen lysine, 2-oxoglutarate 5-

487 dioxygenase 2 (Plod2). Both Plscr4 and Plod2 had local eQTL on chromosome 9. *Plscr4* is a membrane protein that is involved in the organization of phospholipids and 488 interacts with the CD4 receptor of T lymphocytes (PY et al. 2009). It is up-regulated with 489 490 HFD feeding (Song et al. 2012). Plod2 hydroxylates lysine residues and is involved in remodeling of the extracellular matrix (GILKES et al. 2013) and fibrosis (VAN DER SLOT et 491 al. 2003). Under hypoxic conditions, Plod2 is expressed in hepatocellular carcinoma 492 and is correlated with tumor size and macroscopic intrahepatic metastasis. It is a 493 prognostic factor for disease-free survival (NODA et al. 2012). 494

495

QTL that Interact with Sex: There were 9 QTL with p-values ≤ 0.05 for which genotype 496 interacted with sex (File S9), including 5 clinical chemistry traits and 4 hematology traits. 497 Blood urea nitrogen at 19 weeks (BUN2) had a QTL that interacted with sex on 498 chromosome 10 at 95.85 Mb with a LOD of 11.7 ($p \le 0.001$). Males carrying the 129S1, 499 500 C57BL/6J and WSB alleles were associated with higher BUN and females carrying the 501 PWK allele with lower BUN. We did not perform mediation analysis because we do not 502 have kidney transcript information on these mice. Total bilirubin at 19 weeks (TBIL2) 503 had a QTL that interacted with sex on chromosome 19 at 14.89 Mb with a LOD of 11.1 $(p \le 0.001, Figure 5D)$. Females carrying the NZO allele had higher bilirubin and males 504 carrying the CAST allele had lower bilirubin. Mediation analysis using liver gene 505 506 expression did not reveal a candidate gene. The most significant SNPs in the association mapping on chromosome 19 were near five transcripts: Gm8630, 507 Gm31441, Gm37997, Gm26026 and transducin-like enhancer of split 4 (Tle4). None of 508 the gene models had a QTL. *Tle4* is a transcriptional corepressor factor that regulates 509

510 mouse hematopoiesis and bone development (WHEAT *et al.* 2014), and has also been 511 used for histological application as a podocyte nuclear marker in glomeruli 512 (VENKATAREDDY *et al.* 2014).

513

Liver Expression QTL Mapping: We performed linkage mapping on 12,067 liver 514 515 genes and identified additive QTL (File S10), QTL that interact with sex (File S11) and QTL that interact with diet (File S12). We mapped local and distant eQTL using an 516 additive linkage model, and two models in which sex or diet interacts with genotype. We 517 518 plotted the location of significant QTL versus gene location for each model and found 519 that the additive and sex-interactive models produced local eQTL (Figure 6A & B) and the diet-interactive model did not (Figure 6C). At a significance threshold of 0.05, we 520 found that 8,127 local eQTL out of 9,754 total (83.3%) in the additive model, 332 out of 521 532 (62.4%) in the sex-interactive model and 23 out of 219 (10.5%) in the diet-522 interactive model. We have provided an on-line visualization tool at http://churchill-523 lab.jax.org/qtl/svenson/DO478/. 524

525

XO Females: XO females have been previously reported in high numbers in DO mice (CHESLER *et al.* 2016). In order to search for XO females, we plotted the liver expression of *Xist* as an indicator of X chromosome gene expression versus *Ddx3y* as a marker of Y chromosome gene expression (Figure 7). As expected, females that were dizygous for the X chromosome had high *Xist* expression and low *Ddx3y* expression while males had high *Ddx3y* expression and lower *Xist* expression. There were two females (out of

532 244, 0.82%) that had low Xist expression, consistent with hemizygosity on the X chromosome, and low Ddx3y expression and these samples are XO females. In 533 humans, Turner Syndrome describes females with the XO genotype and is 534 535 characterized by short stature, a propensity for ovarian dysfunction and infertility, and heart defects. The two XO females in our study, one fed chow and the other fed the 536 HFD, had very different phenotypes and were not outliers for any particular trait. One of 537 them, however, was especially resistant to weight gain on HFD, gaining only 5 grams of 538 body weight over the course of the study, and died 4 weeks before the scheduled end of 539 540 the study.

DISCUSSION

544

545 Multi-parent populations are excellent tools for studying the effects of genetic diversity on phenotypic variation because they offer increased genetic diversity, high minor allele 546 547 frequencies and fine recombination block structure. The large number of variants leads to perturbation of genes throughout the genome and the high minor allele frequency 548 produces high power to detect the effects of these polymorphisms. The fine 549 550 recombination block structure leads to fine mapping resolution to identify loci that contain a manageable number of candidate genes. These loci may contain genetic 551 variants that alter either protein structure or transcript levels or both. In fact, many loci in 552 multi-parent crosses may be caused by more than one genetic variant and 553 554 disentangling the signal from these different alleles is a complex process. For the cholesterol loci on chromosomes 1 and 5, we combined association mapping using 555

556 imputed SNPs with mediation analysis using liver transcripts and we identified 557 candidate genes using both missense SNPs and transcript levels. This approach is 558 broadly applicable in the DO and other multi-parent populations, but requires 559 transcriptional profiling in a relevant tissue.

560

561 CHOL levels were associated with two loci on chromosomes 1 and 5. Variation at these loci affected mice of both sexes and on both diets. In contrast, CHOL at eight weeks 562 had a QTL on chromosome 10 with effects that were modified by diet. The HFD 563 564 increased CHOL levels by 35.9% in males and 45.1% in females, indicating that diet 565 increases CHOL levels in most mice. However, DO mice carrying the NOD allele on chromosome 10 have higher CHOL levels than mice carrying other alleles at the same 566 locus. The locus covered several Mb and may contain more than one polymorphism 567 that affects CHOL levels, independent of diet. 568

569

Association mapping on chromosome 1 produced a set of SNPs with high LOD scores 570 571 for which 129S1 and WSB contributed the minor allele. Initially, we expected to find 572 SNPs with this allele pattern that alter the protein structure or expression levels of some gene. However, in this case, we believe that two closely located SNPs in Apoa2, each 573 574 of which is private to either 129S1 or WSB, are influencing CHOL levels. The SNP in 129S1 (rs8258226) has been shown to increase CHOL levels and we hypothesize that 575 the SNP in WSB (rs229811374), which is 2 residues away from rs8258226, may also 576 577 increase CHOL levels. This highlights the complexity of analyses in multi-parent

578 crosses. Had we not known of any candidate genes in this region, we may have been 579 led to consider other genes that are unrelated to CHOL metabolism.

580

Mediation analysis identified several candidate genes on chromosome 1. By its nature, 581 582 mediation analysis is a hypothesis generating analysis. All of the genes, Cfhr1, Ctse 583 and *F13b* are within 10 Mb of each other. Of these, *Ctse* is the only gene that had been previously associated with hypercholesterolemia (ZHENG et al. 2015). The situation is 584 similar for the CHOL peak on chromosome 5. Scarb1 has been associated with 585 586 differences in CHOL levels, but *Trafd1* is a new candidate gene that may have effects of 587 CHOL independent of Scarb1. These findings suggest that some strong associations that appear in MAGIC populations may be due to multiple, tightly linked polymorphisms. 588 If this is true, more sophisticated, multi-locus approaches to candidate gene selection 589 will be needed to find causal genes. In this study, we suggest that both association 590 591 mapping and mediation analysis with transcript levels improve the reliability of candidate gene selection because it allows investigators to search for polymorphisms that affect 592 protein structure or transcript levels. 593

594

595 When we performed liver eQTL mapping, we found local eQTL for both the additive 596 model and the sex-interactive model. This suggests that local polymorphisms in 597 regulatory elements modulate transcript levels constitutively in both sexes and 598 differentially by sex. However, when we mapped liver transcript levels using a model in 599 which diet interacts with genotype, we found very few local eQTL. This suggests that

the response to diet is less influenced by the interaction of diet with local polymorphisms
 affecting transcript levels, we speculate that distant loci are acting through non transcriptional mechanisms such as interactions between proteins (CHICK *et al.* 2016).

603

Our analysis of this large study using DO mice includes a novel multi-tiered approach 604 that has identified plausible candidate genes underlying physiological traits, has 605 extended to considering effects of transcription, and provides compelling evidence for 606 further investigation of the role of novel candidates in driving metabolic traits. We 607 608 present an analysis of the complex interplay of sex and diet and how these factors influence important inter-individual variation in outcome. We found that diet increases 609 many traits related to body size and composition. Interestingly, we observed that a high 610 611 fat, high sucrose diet increased the variance of liver gene expression, suggesting that genotype influences the range of responses to diet. We mapped loci for multiple traits 612 but focused on CHOL to demonstrate the complexity of the underlying genetic loci. We 613 614 note that both association mapping and mediation analysis using liver transcript data help to dissect the causal alleles underlying mapping peaks. Finally, we observe that 615 changes in liver transcription in response to diet are not primarily altered by local 616 617 genetic variants. This suggests that other molecular measurements, such as protein or metabolite levels may be more useful in determining the effects of diet on organisms. 618 619 We have made the phenotype and genotype data fully available to the public and have released an interactive viewer to allow the reader to explore the liver expression QTL 620 data. 621

637

638

Figure 2. Physiological traits in the DO. Each plots shows female (circles) and male (squares) mice on chow (open symbols) and HFD (solid symbols). The open symbols connected by dashed lines show the chow diet group means. The closed symbols connected by solid lines show the HFD group means. (A) Spleen weight did not vary between sexes or diet groups. (B) Lean tissue mass at 12 weeks differed by sex and was not affected by diet. (C) Cholesterol at 19 weeks had both a significant difference

between sexes and diets. (D) Bone mineral density at 21 weeks had one of the most

significant sex by diet interactions, showing a greater response in males to HFD

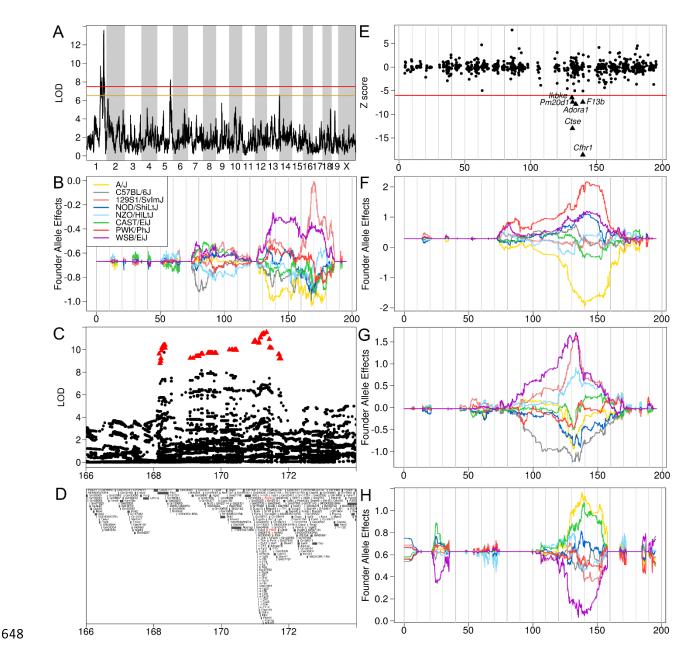

Figure 3. Analysis of cholesterol QTL on chromosome 1. (A) Genome scan of cholesterol at 19 weeks shows peaks on chromosomes 1 and 5. The horizontal axis shows the mouse genome and the vertical axis shows the LOD score. Red and yellow lines are the p = 0.05 and 0.2 significance levels, respectively. The horizontal axis in panels B through H shows the location in Mb on chromosome 1. (B) DO founder allele effects on chromosome 1 for cholesterol at 19 weeks (CHOL2). Each colored line

represents the estimated effect of one of the founder alleles along the chromosome. (C) 655 Association mapping near the peak on chromosome 1 shows that the SNPs for which 656 129S1 and WSB contribute the minor allele have the highest LOD scores (red 657 658 triangles). (D) Genes in the region one chromosome 1 shown in panel C. Apoa2 and Pfdn2 are colored in red and are mentioned in the text. (E) Mediation analysis shows 659 that six genes reduce the LOD score by more than 6 standard deviations. The vertical 660 axis shows the Z-score (scaled LOD across all genes). Each point represent the Z-661 score (standardized LOD score reduction) for one gene in the mediation analysis. The 662 genes are located along the horizontal axis. The red line shows Z = -6. DO founder 663 allele effects for liver expression of (F) Cfhr1, (G) Ctse and (H) F13b on chromosome 1. 664

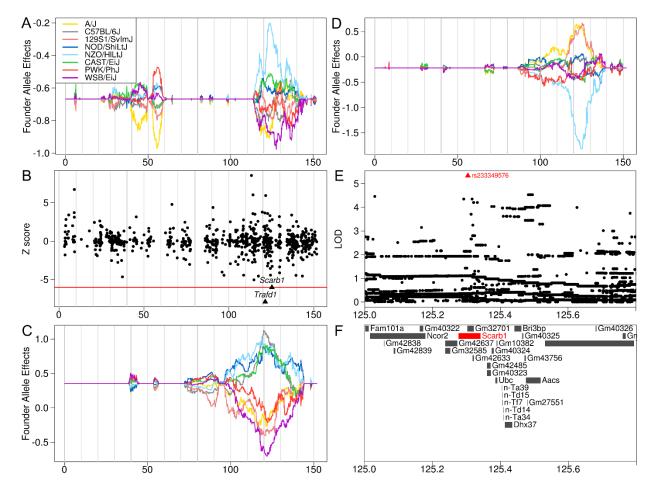

Figure 4. Cholesterol QTL at 19 weeks (CHOL2) on chromosome 5 suggest Trafd1 and 667 Scarb1 as a candidate gene for circulating cholesterol levels. (A) Founder allele effects 668 for CHOL2 show that the NZO allele at 123.7 Mb is associated with higher cholesterol 669 670 levels. Each colored line represents the estimated effects of one founder allele. (B) Mediation analysis of the CHOL QTL on Chr 5 using liver transcripts as mediators. Each 671 672 dot represents the Z-score of the LOD decrease after including one gene in the 673 mapping model. The red line is the Z = -6 threshold. (C) Founder allele effects for liver Trafd1 transcript levels have a similar pattern of allele effects as CHOL2. (D) Founder 674 675 allele effects for liver Scarb1 transcript levels show that DO mice with the NZO allele on 676 chromosome 5 at 123.7 Mb have lower levels of Scarb1. (E & F) Association mapping in

- the interval near the QTL identifies a single SNP (rs233349576) that introduces a stop
- 678 codon into a *Scarb1* transcript.

679

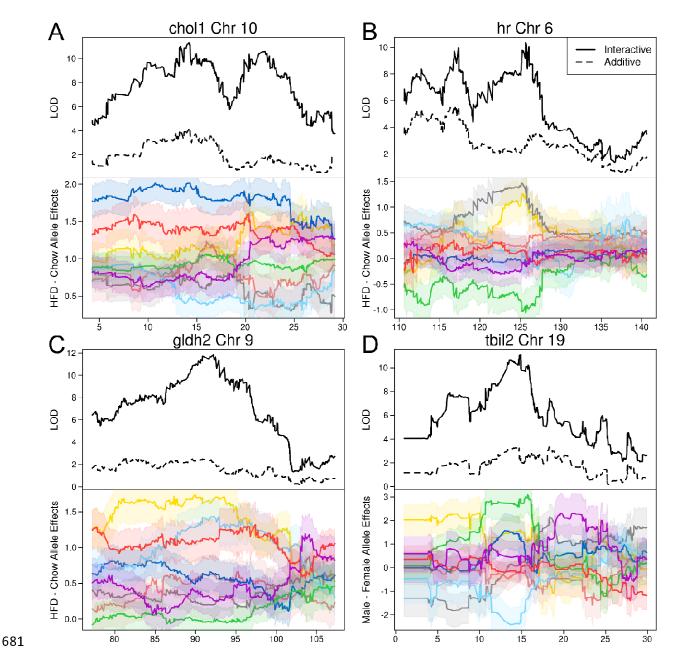

Figure 5. Sex- and diet-interactive QTL plots. Each plot has two panels. The top panel shows the additive LOD (dashed line) and the interactive LOD (solid line). The lower panel shows the difference between the interactive and additive founder allele effects, with standard errors in light shading. Each founder is represented by a separate color: A/J yellow, C57BL/6J grey, 129S1/SvImJ pink, NOD/ShiLtJ cyan, NZO/HILtJ blue, CAST/EiJ green, PWK/PhJ red and WSB/EiJ purple. (A) Cholesterol at eight weeks had

a diet-interactive QTL on chromosome 10. (B) Heart rate had a diet-interactive QTL on

chromosome 6. (C) Glutamate dehydrogenase at 19 weeks had a diet-interactive QTL

on chromosome 9. (D) Bilirubin at 19 weeks had a sex-interactive QTL on chromosome
