204

205 **Abstract**

206 Childhood aggressive behavior (AGG) has a substantial heritability, with limited success in genome-
207 wide association studies. Here we present a genome-wide association meta-analysis (GWAMA) of
208 childhood AGG, in which all phenotype measures across age from multiple assessors were included.
209 We analyzed phenotype assessments for a total of 328 935 observations from 87 485 children aged
210 between 1.5 and 18 years, while accounting for sample overlap. We also meta-analyzed within
211 subsets of the data – i.e. within rater, instrument and age. SNP-heritability for the overall meta-
212 analysis (AGG_{overall}) was 3.31% (SE=0.0038). We found no genome-wide significant SNPs for AGG_{overall}.
213 The gene-based analysis returned three significant genes: *ST3GAL3* ($P=1.6E-06$), *PCDH7* ($P=2.0E-06$)
214 and *IPO13* ($P=2.5E-06$). All three genes have previously been associated with educational traits.
215 Polygenic scores based on our GWAMA significantly predicted aggression in a holdout sample of
216 children (variance explained = 0.44%) and in retrospectively assessed childhood aggression (variance
217 explained = 0.20%). Genetic correlations (r_g) among rater-specific assessment of AGG ranged from
218 $r_g=0.46$ between self- and teacher-assessment to $r_g=0.81$ between mother- and teacher-assessment.
219 We obtained moderate to strong r_g 's with selected phenotypes from multiple domains, but hardly
220 with any of the classical biomarkers thought to be associated with AGG. Significant genetic
221 correlations were observed with most psychiatric and psychological traits (range $|r_g|$: 0.19 – 1.00),
222 except for obsessive-compulsive disorder. Aggression had a negative genetic correlation ($r_g \approx -0.5$)
223 with cognitive traits and age at first birth. Aggression was strongly genetically correlated with
224 smoking phenotypes (range $|r_g|$: 0.46 – 0.60). The genetic correlations between aggression and
225 psychiatric disorders were weaker for teacher-reported AGG than for mother- and self-reported
226 AGG. The current GWAMA of childhood aggression provides a powerful tool to interrogate the rater
227 specific genetic etiology of AGG.

228

229

230 **Introduction**

231 There is a variety of phenotypic definitions of aggressive behavior (AGG), from broadly defined
232 externalizing problems to narrow definitions like chronic physical aggression [1]. Generally any action
233 performed with the intention to harm another organism can be viewed as AGG [2, 3]. AGG is
234 considered a common human behavior [4], with people varying in the degree of AGG they exhibit [5].
235 Children typically display AGG early in life, after which symptoms tend to diminish [6, 7], although in
236 some individuals AGG persists into adulthood [8]. AGG is also part of numerous childhood and adult
237 disorders [9], including oppositional defiant disorder (ODD) and conduct disorder (CD)[10]. In its
238 extreme forms, AGG may be considered a disorder by itself – inflicting a huge personal and financial
239 burden on the individual, their relatives, friends, and society as a whole [11]. In general population
240 studies, AGG is commonly treated as a quantitative trait, and pathological AGG has been argued to be
241 best seen as the extreme end of such a continuum [12–14]. Childhood AGG co-occurs with many other
242 behavioral, emotional, and social problems [15, 16] and is associated with increased risk of developing
243 negative outcomes later in life, including cannabis abuse [17], criminal convictions [18], anxiety
244 disorder [19], or antisocial personality disorder [20]. Not all associated outcomes are harmful [21]. For
245 example, children who learn to control their impulses and apply aggressive acts as a well-timed
246 coercion strategy are generally more liked by their peers and score higher on social dominance [22].

247 Despite a heritability of roughly 50% [5, 23], genome-wide association studies (GWASs) on
248 AGG have not identified genome-wide significant loci that replicated [1]. Childhood cohorts often have
249 rich longitudinal data and assessments from multiple informants and we aimed to increase power to
250 detect genomic loci via multivariate genome-wide association meta-analysis (GWAMA) across
251 genetically correlated traits [24, 25]. In AGG, twin studies have reported moderate to high genetic
252 correlations among instruments, raters, and age [26–29]. Childhood behavior can be context
253 dependent, with teachers, fathers, and mothers each observing and rating aggression against a
254 different background. Teachers are typically unrelated to the child, and see the child in the context of
255 a structured classroom and can judge the child’s behavior against that of other pupils. Parents share

256 part of their genome with their offspring and, most often, a household. Parental genomes also
257 influence the home environment, and it is predominantly within this context that parents observe the
258 child's behavior. Multiple assessments of aggression by teachers, fathers, and mothers, by different
259 instruments and at different ages, provides information that may be unique to a specific context and
260 therefore may capture context-dependent expression of AGG. These considerations support an
261 approach in which all AGG data are simultaneously analyzed, while retaining the ability to analyze the
262 data by rater. Our analyses include repeated observations on the same subject, which requires
263 appropriate modeling of the clustered data, since the covariance between test statistics becomes a
264 function of a true shared genetic signal and the phenotypic correlation among outcomes [29]. We
265 developed an approach that allowed inclusion of all measures for a child – e.g. from multiple raters at
266 multiple ages – and resolved issues of sample overlap at the level of the meta-analysis. By doing so we
267 make full use of all data and maximize statistical power for gene discovery. At the same time, by
268 aggregating data at the level of the meta-analysis we retain the flexibility to estimate r_g 's between
269 AGG at different ages, by different raters and instruments, and test how AGG assessed by multiple
270 raters differ in the r_g with other phenotypes.

271 Data on AGG from parent-, teacher- and self-report in boys and girls were collected in 29
272 cohorts from Europe, USA, Australia, and New-Zealand with 328 935 observations from 87 485
273 participants, aged 1.5 to 18 years. First, we combined all data to produce the largest GWAMA on
274 childhood AGG to date. SNP-based association tests were followed up by gene-based analyses. We
275 computed polygenic scores (PGSs) to test the out-of-sample prediction of AGG to explore the
276 usefulness of our GWAMA in future research [30]. To assess genetic pleiotropy between AGG and
277 associated traits, we estimated r_g 's with a preselected set of external phenotypes from multiple
278 domains – with a focus on psychiatric and psychological traits, cognition, anthropometric and
279 reproductive traits, substance use, and classic biomarkers of AGG, including testosterone levels.
280 Second, meta-analyses were done by rater, instrument, and age. We estimated r_g 's across these

281 assessments of AGG. To identify context-specific genetic overlap with the external phenotypes, r_g 's
282 were also estimated between rater-specific assessments of AGG and the external phenotypes.

283

284 **Methodology**

285 **Data description**

286 Extended description of the cohorts and phenotypes is supplied in the Supplemental Text and
287 Supplementary Tables 1-9. Cohorts with assessment of AGG in genotyped children and adolescents
288 took part in the meta-analysis. AGG was assessed on continuous scales, with higher scores indicating
289 higher levels of AGG. Within cohort, samples were stratified by (1) rater, (2) instrument and (3) age,
290 maintaining at least 450 observations in each stratum. We ran a univariate GWAS for each stratum
291 within each cohort (Supplementary Table 8). To account for dependence within cohort in the meta-
292 analysis (see Supplementary Text), each cohort supplied the phenotypic covariance matrix between
293 the AGG measures (Supplementary Table 10) and the degree of sample overlap (Supplementary
294 Table 11) between the different strata. Supplementary Figure 1 shows the distribution of phenotypic
295 correlations across all AGG measures. We assumed no sample overlap across cohorts, and
296 phenotypic correlations among cohorts were set to zero and omitted from Supplementary Figure 1.
297 Phenotypic correlations of zero also correspond to independent samples within a cohort. For GWASs
298 with sample overlap, most phenotypic correlations ranged between 0.1 and 0.4, with a median value
299 of 0.29. When stratified by rater, phenotypic correlations were more heavily centered around 0.4
300 (see Supplementary Figure 1). The maximum number of correlations within cohort at a specific age is
301 three based on four raters, with the largest number of observations within age-bin around age 12
302 years. Within this age group, phenotypic correlations among raters ranged between 0.22 and 0.65,
303 with a median of 0.34. The lowest phenotypic correlations were seen between teachers and parents.
304 Since limited data were available on individuals of non-European ancestry, we restricted analyses to
305 individuals of European ancestry.

306 In total, 29 cohorts contributed 163 GWASs, based on 328 935 observations from 87 485
307 unique individuals (Supplementary Table 2). Children were 1.5 to 18 years old at assessment, or
308 retrospectively assessed at these ages. Cohorts supplied between 1 and 26 univariate GWASs.
309 Approximately 50% of the subjects were males. Most GWASs were based on maternal- (52.4%) and
310 self-assessment (25.1%), with the remainder based on teacher (12.4%) and paternal report (10.1%).
311 After QC, applied to the univariate GWASs, between 3.47M SNPs and 7.28M SNPs were retained for
312 meta-analysis (see Supplementary Figure 2 and Supplementary Table 9).

313

314 **Meta-analysis**

315 Within cohort measures of AGG may be dependent due to including repeated measures of AGG over
316 age and measures from multiple raters. To account for the effect of sample overlap, we applied a
317 modified version of the multivariate meta-analysis approach developed by Baselmans *et al* [25] (see
318 Table 1). Instead of estimating the dependence among GWASs based on the cross-trait-intercept
319 (CTI) with linkage disequilibrium score regression (LDSC)[29, 31], the expected pairwise CTI value
320 was calculated (Table 1) using the observed sample overlap and phenotypic covariance. The
321 effective sample size (N_{eff}) was approximated by the third formula in Table 1. When there is no
322 sample overlap (or a phenotypic correlation equal to zero) between all GWASs (i.e. CTI is an identity
323 matrix), N_{eff} is equal to the sum of sample sizes.

324 First, we meta-analyzed all available GWASs (AGG_{overall}). Second, we meta-analyzed all
325 available data within rater (rater-specific GWAMAs). Third, rater-specific age-bins were created for
326 mother- and self-reported AGG based on the mean ages of the subjects in each GWAS (age-specific
327 GWAMA). To ensure that the age-specific GWAMAs would have sufficient power for subsequent
328 analyses, age-bins were created such that the total *univariate* number of observations (N_{obs})
329 exceeded 15 000 (see Supplementary Text and Supplementary Table 12). For father- and teacher-
330 reported AGG there were insufficient data to run age-specific GWAMAs. Fourth, we performed

331 instrument-specific GWAMAs for (1) the ASEBA scales and (2) for the SDQ, because for these two
332 instruments the total *univariate* N_{obs} was over 15 000.

333 SNPs that had $\text{MAF} < 0.01$, $N_{\text{eff}} < 15\ 000$, or were observed in less than two cohorts were
334 removed from further analyses. SNP-heritabilities (h_{SNP}^2) were estimated using LDSC [31]. r_g 's were
335 calculated across stratified assessments of AGG using LDSC [29]. To ensure sufficient power for the
336 genetic correlations, r_g was calculated across stratified assessments of AGG if the Z-score of the
337 h_{SNP}^2 for the corresponding GWAMA was 4 or higher [29].

338

339 **Gene-based tests**

340 For $\text{AGG}_{\text{overall}}$, a gene-based analysis was done in MAGMA [32]. The gene-based test combines *P*-
341 values from multiple SNPs to obtain a test statistic for each gene, while accounting for LD between
342 the SNPs. From the MAGMA website (see URLs) we obtained (1) a list of 18 087 genes and their
343 start- and end-positions, and (2) pre-formatted European genotypes from 1 000 Genomes phase 3
344 for the reference LD. We applied a Bonferroni correction for multiple testing at $\alpha = 0.05/18\ 087$. A
345 lookup for significant results was performed in GWAS Catalog and PhenoScanner (see URLs).

346

347 **Polygenic Scores**

348 All data were meta-analyzed twice more, once omitting all data from the Netherlands Twin Register
349 (NTR) and once omitting the Australian data from the Queensland Institute for Medical Research
350 (QIMR,) and the Mater-University of Queensland Study of Pregnancy (MUSP). As the NTR target
351 sample we considered mother-reported AGG at age 7 ($N = 4\ 491$), which represents the largest NTR
352 univariate stratum. In the QIRM participants, we tested whether our childhood AGG PGS predicted
353 adult retrospective assessment of their own CD behavior during adolescence ($N = 10\ 706$). We
354 allowed for cohort-specific best practice in the polygenic score analysis. In the NTR, we created 16
355 sets of PGSs in PLINK1.9 [33], with *P*-value thresholds between 1 and $1.0\text{E-}05$ (see Supplementary
356 Table 13). The remaining SNPs were clumped in PLINK. We applied an r^2 -threshold of 0.5 and

357 minimum clumping distance of 250 000 base pair positions [33]. Age, age^2 , sex, first five ancestry-
358 based principal components, a SNP-array variable, and interaction terms between sex and age, and
359 sex and age^2 were defined as fixed effects. To account for relatedness, prediction was performed
360 using generalized equation estimation (GEE) as implemented in the “gee” package (version 4.13-19)
361 in R (version 3.5.3). GEE applies a sandwich correction over the standard errors to account for
362 clustering in the data [34]. To correct for multiple testing, we applied an FDR correction at $\alpha=0.05$ for
363 16 tests. QIMR excluded SNPs with low imputation quality ($r^2 = 0.6$) and MAF below 1% and selected
364 the most significant independent SNPs using PLINK1.9 [35] (criteria linkage disequilibrium $r^2 = 0.1$
365 within windows of 10 MBp). We calculated different PGS for seven P-value thresholds ($p < 1e-5$, p
366 < 0.001 , $p < 0.01$, $p < 0.05$, $p < 0.1$, $p < 0.5$, and $p < 1.0$) of the GWAS summary statistics. PGS were
367 calculated from the imputed genotype dosages to the 1 000 Genomes (Phase 3 Release 5) reference
368 panel. We fitted linear mixed models, which controlled for relatedness using a Genetic Relatedness
369 Matrix (GRM) and covariates sex, age, two dummy variables for the GWAS array used, and the first
370 five genetic principal components. The parameters of the model were estimated using GCTA 1.9 [36]
371 The linear model was as follows:

$$CD \text{ symptom score} = intercept + Covariates * b + c * PGS + G$$

372 where b and c represent the vectors of fixed effects; and $G \sim N(0, GRM * \sigma^2 G)$ represents the
373 random effect that models the sample relatedness, with GRM being the N by N matrix of
374 relatedness estimated from SNPs and $N=10\,706$ is the number of individuals.

375

376 **Genetic correlations with external phenotypes**

377 We computed r_g 's between $AGG_{overall}$ and a set of preselected outcomes ($N=46$; collectively referred
378 to as “external phenotypes”; Supplementary Table 14). Phenotypes were selected based on
379 established hypotheses with AGG and the availability of sufficiently powered GWAS summary
380 statistics. We restricted r_g 's to phenotypes for which the Z-scores of the LDSC-based $h_{SNP}^2 \geq 4$ [29].
381 Next, we estimated r_g 's for all rater-specific assessments of AGG (except for father-reported AGG).

382 Genomic Structural Equation Modelling (Genomic SEM)[37] was applied to test if r_g 's were
383 significantly different across raters. Specifically, for every phenotype, we tested whether (1) all three
384 r_g 's between the external phenotype and rater-specific assessment of AGG, i.e. mother, teacher or
385 self-ratings, could be constrained at zero, and (2) whether r_g 's could be constrained to be equal
386 across raters. A χ^2 difference test was applied to assess whether imposing the constraints resulted
387 in a significant worse model fit compared to a model where the r_g 's between the phenotype and
388 three rater-specific assessment of AGG were allowed to differ. We applied an FDR correction at
389 $\alpha=0.05$ over two models for 46 external phenotypes, for a total of 92 tests. An FDR correction for $4 \times$
390 $46=184$ tests was applied to correct for multiple testing of whether the genetic correlations were
391 significantly different from zero.

392

393 **Results**

394 **Overall GWAMA**

395 We first meta-analyzed the effect of each SNP across all available univariate GWASs. Assuming an
396 N_{eff} of 151 741, the h^2_{SNP} of AGG_{overall} was estimated at 3.31% (SE=0.0038). The mean χ^2 -statistic was
397 1.12 along with an LDSC-intercept of 1.02 (SE=0.01). This indicated that a small, but significant, part
398 of the inflation in test statistics might have been due to confounding biases, which can either reflect
399 population stratification or subtle misspecification of sample overlap within cohorts. No genome-
400 wide significant hits were found for AGG_{overall} (Figure 1). The list of suggestive associations ($P<1.0E-05$)
401 is provided in Supplementary Table 15. SNPs were annotated with SNPnexus (see URLs). The
402 strongest association, in terms of significance, was located on chromosome 2 (rs2570485; $P=2.0E-$
403 07). The SNP is located inside a gene desert, without any gene in 400Kbp in any direction. The
404 second strongest independent association was found with rs113599846 ($P=4.3E-07$), which is
405 located inside an intronic region of *TNRC18* on chromosome 7. None of the suggestive associations
406 have previously been reported for AGG or AGG-related traits [1].

407 We tested previously reported genome-wide significant associations for AGG [1] and
408 performed a lookup in $AGG_{overall}$. We restricted lookup to associations with autosomal SNPs that
409 were found in samples of European ancestry, resulting in three loci. One genome-wide significant hit
410 was reported for adult antisocial personality disorder ($rs4714329$; $OR=0.63^1$; $P=1.64E-09$)[38]. The
411 same SNP, however, had an opposite direction of effect in $AGG_{overall}$ ($\beta=0.0022$; $P=0.41$). Tielbeek *et*
412 *al* [39] reported two genome-wide significant hits for antisocial behavior, one on chromosome 1
413 ($rs2764450$) and one on chromosome 11 ($rs11215217$). While both SNPs have the same direction of
414 effect, neither SNP is associated with $AGG_{overall}$ (both $P>0.5$).

415

416 **Gene-based analysis**

417 After correction for multiple testing, the gene-based analysis returned three significant results
418 (Supplementary Table 16): *ST3GAL3* (ST3 beta-galactoside alpha-2,3-sialyltransferase3; $P=1.6E-06$),
419 *PCDH7* (protocadherin 7; $P=2.0E-06$) and *IPO13* (importin 13; $P=2.5E-06$). *ST3GAL3* codes for a type II
420 membrane protein that is involved in catalyzing the transfer of sialic acid from CMP-sialic acid to
421 galactose-containing substrates. *ST3GAL3* has been implicated in 107 GWASs, most notably on
422 intelligence and educational attainment. The top SNP in *ST3GAL3* ($rs2485997$; $P=2.48E-06$) is in
423 strong LD ($r^2>0.8$) with several other SNPs inside the gene body of *ST3GAL3* and in moderate LD
424 ($r^2>0.6$) with SNPs in several neighboring genes (Supplementary Figure 3). *PCDH7* codes for a protein
425 that is hypothesized to function in cell-cell recognition and adhesion. *PCDH7* has been implicated in
426 196 previous GWASs, for example educational attainment and adventurousness. The top SNP for
427 *PCDH7* ($rs13138213$; $P=1.44E-06$) is in strong LD ($r^2>0.8$) with a small number of other closely located
428 SNPs and the signal for the gene-based test appears to be driven by two independent loci
429 (Supplementary Figure 4). *IPO13* codes for a nuclear transport protein. *IPO13* has been implicated in
430 the UKB GWASs on whether a person holds a college or university degree and intelligence. The top

¹ odds ratio was signed to the other allele in the original study

431 SNP (rs3791116; $P=1.19E-05$) is in moderate to strong LD with multiple SNPs (Supplementary Figure
432 5), including SNPs in the neighboring *ST3GAL3* gene.

433

434 **Polygenic prediction**

435 In children, 11 out of 16 polygenic scores were significantly correlated with mother-reported AGG in
436 7-year-olds (Figure 2A) after correction for multiple testing. The scores explained between 0.036%
437 and 0.44% of the phenotypic variance. The significant correlations consistently emerged when
438 scores including SNPs with P-values above 0.002 in the discovery GWAS were considered. In the
439 retrospective assessments of adolescent CD, the PGS calculated at various thresholds (Figure 2B)
440 explained up to 0.2% of the variance in symptom sum scores. Generally, CD is significantly predicted
441 at most thresholds, although, as we would expect based on the SNP-heritability of $AGG_{overall}$, the
442 proportion of explained variance is small.

443

444 **Genetic correlation with external phenotypes**

445 Genetic correlations between $AGG_{overall}$ and a set of preselected external phenotypes are shown in
446 Figure 3 and Supplementary Table 17. These phenotypes can broadly be grouped into psychiatric
447 and psychological traits, substance use, cognitive ability, anthropometric traits, classic biomarkers of
448 AGG, reproductive traits, and sleeping behavior. We included childhood phenotypes (e.g. birth
449 weight and childhood IQ) and disorders (e.g. ADHD and autism spectrum disorder [ASD]), but the
450 majority of phenotypes were adult characteristics or characteristics measured in adult samples.
451 After correction for multiple testing, 36 phenotypes showed a significant r_g with $AGG_{overall}$ ($P<0.02$).
452 In general, the highest positive correlations were seen with psychiatric traits, notably ADHD, ASD,
453 and major depressive disorder (MDD). The largest negative genetic correlations were found for age
454 at smoking initiation, childhood IQ, and age at first birth. Based on the biomarker-aggression
455 literature, we tested for the presence of genetic correlations between $AGG_{overall}$ and lipids, heart rate,
456 heart rate variability, and testosterone levels. Very low genetic correlations were observed for

457 AGG_{overall}, and these biomarkers, with in many cases the sign of the genetic correlation opposite to
458 what was expected based on the literature on biomarkers of AGG.

459

460 **Stratified assessment of childhood aggressive behavior**

461 Separate meta-analyses were carried out for raters, instruments and age. None of these GWAMAs
462 returned genome-wide significant hits. Manhattan plots for the four rater-specific GWAMAs are
463 shown in Supplementary Figure 6. Estimates of h_{SNP}^2 for rater-specific assessment of AGG are shown
464 in Supplementary Table 18. The lowest h_{SNP}^2 was observed for father-reported AGG ($h_{SNP}^2=0.04$;
465 SE=0.03) and the highest for teacher-reported AGG ($h_{SNP}^2=0.08$; SE=0.02). We estimated r_g between
466 rater-specific assessment of AGG, except for father-reported AGG, which returned a non-significant
467 h_{SNP}^2 . Genetic correlations were 0.67 between AGG_{Mother} and AGG_{Self} (SE=0.10), and 0.81 between
468 AGG_{Mother} and AGG_{Teacher} (SE=0.11), and in both cases significantly lower than 1. A moderate r_g was
469 estimated between AGG_{Self} and AGG_{Teacher} ($r_g=0.46$; SE=0.13).

470 We performed a GWAMA across all GWASs where an ASEBA scale was used (AGG_{ASEBA}) and
471 another GWAMA across all GWASs for the SDQ (AGG_{SDQ}). SNP-heritabilities for AGG_{ASEBA} and AGG_{SDQ}
472 were 0.031 (SE=0.0099) and 0.026 (SE=0.0086), respectively. The GWAMAs were insufficiently
473 powered to estimate r_g across instrument-specific assessment of AGG.

474 Age-specific GWAMAs were performed for mother- and self-reported AGG, which made up
475 77.5% of the data. Mother-reported data were split into seven age-bins and self-reported data into
476 three (Supplementary Table 12). Estimates of the h_{SNP}^2 for each age-specific GWAMA can be found
477 in Supplementary Table 19. For mother-reported AGG, h_{SNP}^2 ranged between 0.012 and 0.078. For
478 self-reported AGG, the highest h_{SNP}^2 was seen for the retrospective data ($h_{SNP}^2=0.12$; SE=0.03), which
479 also showed a significantly inflated intercept (1.05; SE=0.01). r_g could only be estimated between
480 AGG_{M7}, AGG_{S13} and AGG_{SR} (Supplementary Table 20).

481

482 **Genetic correlation between rater-specific assessment of AGG and external phenotypes**

483 We estimated rater-specific r_g 's with the external phenotypes, except for father-reported AGG, and
484 tested if these r_g 's could be constrained to be equal across mothers, teachers and self-ratings. For
485 ADHD, ASD, MDD, schizophrenia, well-being, and self-reported health, constraining the r_g 's to be
486 equal across rater resulted in significantly worse model fit (Supplementary Table 21). For all these
487 phenotypes, r_g 's with teacher-reported AGG were consistently lower compared to mother- and self-
488 reported AGG (Supplementary Figure 7 and Supplementary Table 17). For lifetime cannabis use,
489 genetic correlations also could not be constrained to be equal across raters. Here, a relatively strong
490 r_g was found with self-reported AGG ($r_g=0.36$; $SE=0.08$) compared to teacher- ($r_g=0.13$; $SE=0.07$) and
491 mother-reported AGG ($r_g=0.08$; $SE=0.08$).

492

493 Discussion

494 We present the largest genome-wide association meta-analysis (GWAMA) of childhood aggressive
495 behavior (AGG) to date. The gene-based analysis implicated three genes, *PCDH7*, *ST3GAL3* and *IPO13*,
496 based on the overall meta-analysis (AGG_{overall}), which did not return genome-wide significant SNPs.
497 Lead SNPs in the implicated genes were related to educational outcomes, but did not reach genome-
498 wide significance and these loci require further evidence before being considered as AGG risk
499 variants. Polygenic scores (PGS) predicted childhood AGG and retrospectively assessed adolescent
500 CD. Stratified analyses within AGG generally returned moderate to strong genetic correlations across
501 raters. We found substantial genetic correlations between AGG_{overall} and a list of preselected external
502 phenotypes from various domains, including, psychiatry and psychology, cognition, anthropometric
503 and reproductive traits. Most notably was the perfect r_g between AGG_{overall} and ADHD ($r_g=1.00$;
504 $SE=0.07$). This is in line with the moderate-to-strong phenotypic correlations that have consistently
505 been found across sex-, rater-, age- and instrument-specific assessment of AGG with attention
506 problems and hyperactivity [15]. Significant genetic correlations were further observed with other
507 psychiatric and psychological traits (range $|r_g|$: 0.19 – 0.55). Negative genetic correlations ($r_g \sim -0.5$)
508 were found with all three traits from the cognitive domain. Genetic correlations were positive with

509 smoking initiation ($r_g=0.55$; $SE=0.04$) and smoking quantity ($r_g=0.46$; $SE=0.06$), and negative with age
510 at smoking initiation ($r_g=-0.60$; $SE=0.09$).

511 We examined genetic correlations with classical biomarkers of aggressive behavior. Higher
512 levels of aggression have been associated with lower levels of LDL [40] and lower resting heart rate
513 [41, 42]. We found a positive, albeit weak, r_g between $AGG_{overall}$ and LDL ($r_g=0.15$; $SE=0.07$), which
514 has an opposite sign than what was expected based on the literature [39]. More broadly, except for
515 HDL ($r_g=-0.13$; $SE=0.07$), all measures of lipid levels returned significant positive r_g 's with $AGG_{overall}$,
516 albeit weakly ($r_g<0.2$). No heart rate measure showed a significant genetic correlation with $AGG_{overall}$.
517 The relationship between testosterone levels and (childhood) AGG in the literature is, at best,
518 unclear. A positive association between AGG and testosterone is often assumed, but the relation
519 may be more complex [43]. Both positive and negative phenotypic correlations have been found and
520 seem context-dependent [44]. We found significant negative, r_g 's between $AGG_{overall}$ and
521 testosterone levels in males and females ($|r_g|<0.15$). These should be interpreted with some caution
522 because of the design of the GWA studies: AGG was measured in children and young adolescents
523 whereas testosterone levels were measured in adults in the UK Biobank [45], and genetic stability of
524 testosterone levels might be low, at least for males [46]. Genetic correlations with reproductive
525 traits showed a positive relation with having more children ($r_g=0.27$; $SE=0.08$) and having offspring
526 earlier in life ($r_g=-0.60$; $SE=0.06$), tending to confirm that not all associated outcomes are harmful.

527 The stratified design of our study also allowed for examination of the genetic etiology of
528 AGG in subsets of the data and examination of genetic correlations among raters. The r_g between
529 AGG_{Mother} and $AGG_{Teacher}$ ($r_g=0.81$; $SE=0.11$) was high, but less than unity, and is in line with previous
530 findings of rater-specific additive genetic effects in childhood AGG [47]. Most external phenotypes
531 showed comparable r_g 's with mother-, self-, and teacher-reported AGG. For ADHD, ASD, MDD,
532 schizophrenia, well-being, and self-reported health, r_g 's differed significantly across raters. Weaker
533 r_g 's were consistently found in teacher-reported AGG compared to mother- and self-reported AGG.
534 These findings indicate the presence of rater-specific effects when considering the genetic

535 correlation of AGG with other outcomes. r_g 's are generally stronger in the psychopathology and
536 psychological domains. A lack of power, however, seems insufficient to explain why we found
537 weaker r_g 's between $AGG_{Teacher}$ and phenotypes from these two domains. Other phenotypes, like
538 smoking behavior, educational attainment or age at first birth, are, like psychopathological
539 phenotypes, highly genetically correlated with $AGG_{overall}$, but, unlike psychopathologies, have near
540 identical r_g 's across raters. The rater-specific effects on r_g 's between childhood AGG and external
541 phenotypes might be limited to psychopathologies, and future research into the genetics of
542 childhood psychopathology might consider these nuances in effects of assessment of childhood AGG
543 from various sources, be that multiple raters, instruments, and ages.

544 Despite the considerable sample sizes, we were still underpowered to compute genetic
545 correlations with external phenotypes while stratifying AGG over age or instrument. Age-stratified
546 GWASs in larger samples across development are a desirable target for future research. Because
547 genetic correlations can be computed between phenotypes for which a well-powered GWAS is
548 available, age-stratified GWAS of many developmental phenotypes, behavioral, cognitive and
549 neuroscientific can be leveraged to better understand development of childhood traits.

550 We note that multivariate results should be interpreted with some caution. While combining
551 data from correlated traits can indeed improve power to identify genome-wide associations,
552 interpreting the phenotype may not be straightforward. In the current GWAMA, we have referred to
553 our phenotype as “aggressive behavior” and interpreted the results accordingly. Aggressive behavior,
554 however, is an umbrella term that has been used to identify a wide range of distinct – though
555 correlated – traits and behaviors [1].

556 Genome-wide association studies are increasingly successful in identifying genomic loci for
557 complex human traits [48] and also in psychiatry, genetic biomarkers are increasingly thought of as
558 promising for both research and treatment. Genetic risk prediction holds promise for adult
559 psychiatric disorders [30] and it seems reasonable to expect the same for childhood disorders. Here
560 we found that polygenic scores explain up to 0.44% of the phenotypic variance in AGG in 7-year-olds

561 and 0.2% of the variance in retrospectively reported adolescent CD. Future studies may explore the
562 utility of these PGSs in illuminating pleiotropy between $AGG_{overall}$ and other traits. A limiting factor in
563 this regard is the relatively low SNP-heritability, which puts an upper bound on the predictive
564 accuracy of PGSs. Since measurement error suppresses SNP-heritability, better measurement may
565 offer an avenue to higher powered GWAS, and subsequently to better PGS. Furthermore, sample
566 sizes for developmental phenotypes, including AGG may need to increase by one to two orders of
567 magnitude before PGS become useful for individual patients.

568 Despite our extensive effort, the first genome-wide significant SNP for childhood AGG has
569 yet to be found. Even in the absence of genome-wide significant loci, however, GWASs aid in
570 clarifying the biology behind complex traits. Our results show that, even without genome-wide
571 significant hits, a GWAS can be powerful enough to illuminate the genetic etiology of a trait in the
572 form of r_g 's with other complex traits. Non-significant associations are expected to capture part of
573 the polygenicity of a trait [31] and various follow up-analyses have been developed for GWASs that
574 do not require, but are aided by, genome-wide significant hits [49]. Polygenic scores aggregate SNP
575 effects into a weighted sum that indicates a person's genetic liability to develop a disorder. While
576 their clinical application is still limited in psychiatric disorders, they can already aid in understanding
577 the pleiotropy among psychiatric and other traits [30]. Similarly, summary statistics-based genetic
578 correlations (r_g) provide insight into the genetic overlap between complex traits [29, 50].

735 **Figures**

736

737 **Figure 1.** Manhattan plot of overall meta-analysis for childhood aggression ($AGG_{overall}$). Red triangles
738 represent SNPs that were included in the significant genes from the gene-based analysis. SNPs for
739 *ST3GAL3* and *IPO13* are included in the same locus on chromosome 1.

740

741 **Figure 2A.** Proportion of explained variance (vertical axis) in childhood aggression at age 7 by
742 polygenic scores from the overall GWAMA for multiple P -value thresholds (horizontal axis). Asterisks
743 indicate scores with a significant beta after FDR correction for multiple testing at $\alpha=0.05$ for 16 tests.

744

745 **Figure 2B.** Proportion of explained variance (vertical axis) in retrospective adolescent CD (two sided
746 tests). Blue bars indicate positive correlation with the conduct disorder score.

747

748 **Figure 3.** Genetic correlation with external phenotypes. Phenotypes are ordered by domain. Bars
749 indicate 95% confidence intervals.

750

751

752 **Table**

753 **Table 1.** (a) multivariate test statistic in the meta-analysis of results based on overlapping samples.
 754 (b) expected value for the cross-trait-intercept. (c) Effective sample size for a GWAMA.

$Z_{multi,j}$ $= \frac{\sum_{i=1}^P w_{ji} Z_{ji}}{\sqrt{\sum_{i=1}^P w_{ji} V_{ji} + \sum_{i=1}^P \sum_{k=1}^P \sqrt{w_{ji} w_{jk}} CTI_{ik} \text{ for } i \neq k}}$	<p>(a)</p> <p>Multivariate test-statistic for j-th SNP. P is the number of GWASs across which we run the meta-analysis; $w_{ji} = \sqrt{N_{ji} h_{SNP,i}^2}$ is the weight given to the jth SNP in GWAS i, with $h_{SNP,i}^2$ being the SNP-heritability of the trait analyzed in GWAS i; and $V_{ji} = 1$ represents the variance of the distribution of Z_{ji} under the null hypothesis of no effect.</p>
$CTI_{ik} = \frac{N_s r_p}{\sqrt{N_{ji} N_{jk}}}$	<p>(b)</p> <p>Cross-trait-intercept between GWAS i and k. N_s represents the sample overlap; r_p indicates the phenotypic correlation; N_{ji} and N_{jk} are the sample sizes at SNP j for respectively GWASs i and k</p>
$N_{eff} = \sqrt{N^T CTI^{-1} N}$	<p>(c)</p> <p>N is an P-sized vector of sample sizes, and CTI is the $P \times P$ matrix of cross-trait-intercepts.</p>
